Expansion of the superoinferior defect may originate from the oroantral fistula, giving rise to a defect that borders the skull base superiorly and the tongue inferiorly. Therefore, superior and inferior expansion of the defect will extend into the alveolar level, palatal level, paranasal sinuses, orbit, and the anterior base of the skull bone. The size of the defect determines the technique used for reconstruction. The expansion of the anteroposterior defect occurs in the horizontal and sagittal fields with the involvement of the right-left posterior region, and the right-left anterior maxilla. An anterior defect can cause reduced lip movement, scar tissue on the lips, and the collapse of the nose when the nasal bone is removed. Expansion of the mediolateral defect can cause a unilateral defect involving only one maxillary bone, whereas the bilateral defect involves both maxilla. Unilateral defect reconstruction requires less tissue than the reconstruction of bilateral defects. However, this

depends on the tissue conditions, and the reconstruction can be followed by implant placement [24].

Brown et al. [25] classified post-maxillectomy defect into two categories, namely, vertical and horizontal defects. This classification is also reported in the literature review conducted by Bidra et al. [24] Vertical defects are divided into six types: maxillectomy without oronasal fistula, maxillectomy without orbital involvement, maxillectomy with orbital tissue involvement, maxillectomy with orbital enucleation, orbitomaxillary defect, and nasomaxillary defect. Horizontal defects are divided into four types: palate defect without alveolar involvement, unilateral defects less than or equal to half the palate, bilateral defects less than or equal to half the palate, and bilateral defects greater than half the palate (Figures 12, 13).

Figure 12. Vertical defect. (I) Maxillectomy without oronasal fistula, (II) maxillectomy without orbital involvement, (III) maxillectomy with orbital tissue involvement, (IV) maxillectomy with orbital enucleation, (V) orbitomaxillary defect, and (VI) nasomaxillary defect [25].

Figure 13. Horizontal defect. (a) Palate defect without alveolar defect, (b) unilateral defects less than or equal to half the palate, (c) bilateral defects less than or equal to half the palate, and (d) bilateral defects greater than half the palate [25].

SUPRASTRUCTURE MAXILLECTOMY RECONSTRUCTION

Maxillofacial reconstruction can be performed with various materials, such as titanium mesh, hydroxyapatite gel, silica gel, bone, and ribs. Use of autologous material for maxillofacial reconstruction will aggravate the condition after maxillectomy due to injuries to the corresponding donor site [26].

The main goal of mid-facial reconstruction is to improve facial contours, eye volume, and position. The irregularity and thinness of the facial and eye anatomy as well as the contours of the face present obstacles to maxillofacial reconstruction. Titanium mesh is the most commonly used material for maxillofacial and orbital reconstruction. The advantages of using titanium mesh for reconstruction include good fabrication quality, stability, tool flexibility, the absence of tissue damage due to donor requirements, and the short duration of surgery. Post maxillectomy and resection, the defect is always extensive from the maxilla towards the zygoma and orbital floor, thus requiring diverse mesh and plates as well as tissue to protect the mesh [26].

The successful reconstruction of orbital floors with titanium mesh depends on two factors. First is the formation recovery of the individual orbital floor, and the second is the precise position of the titanium mesh installation. Important parameters for mid-facial reconstruction with good aesthetic results are contour recovery, maxillary volume, and eyeball position, as well as rehabilitation of the infraorbital area contour. The eyeball position is maintained by a balance between the orbit volume and intraorbital soft tissue. Balance disorders will cause a decrease in orbital content and can cause enophthalmus, which is a post-maxillectomy problem [26].

Alloplastic materials used for reconstruction must be able to integrate with the body. Titanium is a metal material first discovered by William Gregor in 1791 and used commercially in 1950. It was first used for a medical purpose in 1980. This material is anti-corrosive, elastic, unaffected by temperature changes, and has good bio-compatibility. The chemical composition of this material is capable of producing good integration between titanium and bone without causing fibrosis. Titanium will not inhibit tissue growth even with extensive defects in the maxillofacial region because the material interacts well with the soft tissues of the body [27, 28].

Figure 14. Virtual image of post-maxillectomy defect [26].

Although titanium mesh is an ideal choice for the reconstruction of orbit floors, some risks remain. The main risks are infection and exposure to titanium mesh, especially for tumor patients undergoing radiotherapy. Hypovascular tissue and extensive fibrosis after radiotherapy increase the risk of infection and exposure to titanium mesh (Figures 14, 15) [27].

Figure 15. Titanium mesh used in the reconstruction of post-maxillectomy defect [26].

CASE REPORT

This paper presents the case of a patient with fibrous dysplasia treated with suprastructure maxillectomy. Reconstruction was later performed using titanium mesh and muscular buccal muscle slings.

An 11-year-olds girl was referred to the Oncology ENT division for reconstruction after the removal of a left maxillary tumor through suprastructure maxillectomy. The patient had a complaint of swelling in the left cheek accompanied by left eye exophthalmus and decreased vision starting 6 months earlier. She also complained of nasal congestion without nosebleeds and pain starting 4 months before hospital admission.

The patient was examined with computer tomography, which showed the compacting of the maxillary sinus, ethmoid and left sphenoid, with multiple calcification complexes in the ethmoid sinus accompanied by ethmoid, maxillary, and left sphenoid bone destruction extending to the left retrobulbar region, suspected as a sinonasal mass. Examination of magnetic resonance imaging shows a suspected benign solid tumor of the left ethmoid sinus with left orbital thrusting and a left osteomeatal complex that causes left proptosis, left sphenoid, and maxillary sinusitis (Figures 16).

The patient was diagnosed with suspected maxillary fibroma, and suprastructure maxillectomy was planned by Oncology division Department of Otorhino-laryngology Head and Neck Surgery. The tumor tissue was sent to the Anatomy Pathology Department for histopathological examination. Post-maxillectomy, enophthalmus was found in the left eye with a posterior movement when the eyes were tightly closed. The patient was referred to the Plastic Reconstruction division Department of Otorhinolaryngology Head and Neck Surgery for post-maxillectomy defect reconstruction.

Figure 16. Asymetrical and protrution eye.

After tumor removal surgery, defects occurred in several locations, including the anterior maxillary wall, medial maxillary wall, inferior wall of the left orbital rhyme, and enophthalmus, with a posterior movement when the eyes were closed firmly. At the beginning of the reconstruction, a sharp dissection was performed to expose the left buccal mucosa and muscle. Afterwards, a sling was created by sewing the end of the muscle to the medial canthus to form eye pads, followed by suturing the left septal mucosa to the medial canthus of the left eye. A titanium plate was sewn onto the buccal muscle sling to match the projection of the nasal lateral wall and form the medial wall of the left maxilla. The titanium mesh was shaped in accordance with the shape of the anterior maxillary wall and then sewn and fixed using screws. The reconstructed defect was closed using subcutaneous sutures following the directions for the Weber–Ferguson incision with Lynch extension to the gingivobuccal.

After the surgery, the patient was given ceftriaxone 2 gr once a day, ranitidine 50 mg twice a day, ketorolac 30 mg three times a day, and tranexamic acid 500 mg three times a day. The patient was fed a liquid diet through the nasogastric tube. An edema of the left orbit appeared and decreased on the second day after surgery, and the left eye appeared parallel to the right. The patient was treated for 5 days in the hospital after the procedure, and the sutures were removed 1 week later. The histological result showed that the fibro-osseous lesion was in accordance with fibrous dysplasia (Figures 17-23).

LITERATURE SEARCHING METHOD

A literature search of PubMed, ScienceDirect, and ClinicalKey was performed. The keywords used were “maxillary and orbital floor defect reconstruction” and “titanium mesh,” with clinical questions regarding the effect of titanium mesh use in the surgical management

of suprastructure maxillectomy. The search yielded 310 articles. After screening the results for the latest articles, multiple publications, and compatibility to clinical questions, three relevant articles were obtained (Figure 24).

Figure 24. A literature search of PubMed, ScienceDirect, and ClinicalKey with clinical questions regarding the effect of titanium mesh use in the surgical management of suprastructure maxillectomy.

On the basis of the research by Zhang et al. [26], the use of titanium mesh material is more advantageous than the use of autograph materials. The material provides good results for maxillary and orbital reconstruction due to the complex characteristics of the cheeks and orbit contours. Titanium mesh can follow the contour and is therefore very good at closing defects. Expertise and caution during reconstruction are essential when performing facial reconstruction.

The use of titanium mesh for defect reconstruction after removal of the maxillary tumor leads to good results in repairing the anterior maxillary wall and the orbit base according to the report by Lv et al. [29].

A report by Motiee-Langroudi et al. [28] described the use of titanium mesh for maxillary and orbital base defect reconstruction. The combination of the use of fascia with titanium mesh prevents the fall of orbital fat through the titanium mesh hole.

DISCUSSION

Defect reconstruction post-suprastructure maxillectomy for patients with maxillary fibrous dysplasia is a difficult and complicated procedure. According to the report by Duan et al. [5], the incidence of fibrous dysplasia is equal to 1:30,000 individuals, comprising 7.5% of all benign bone tumors. The percentage of benign tumors managed using the open

maxillectomy technique was 26.4% among the 65 cases recorded from 2000 to 2009 in Malaysia.

The mid-facial area is an important structure on the face due to its anatomical and structural characteristics and functions related to breathing, phonation, chewing, swallowing, vision, and smelling.

The maxillary supporting wall, which is divided into vertical and horizontal supporting walls, is an important component of the facial structure. Vertical walls play a role in maintaining the mid-facial area in an upright position.

The main symptom of fibrous dysplasia is painless swelling of the facial bones, especially the maxilla and mandible. Symptoms of the eyes and nose can occur along with the growth of the lesion. Pushing towards the eyes will result in visual disturbances, whereas pushing towards the nose will result in nasal congestion. These symptoms are in accordance with fibrous dysplasia. Open surgery with maxillectomy is the treatment of choice, and maxillectomy has a variety of classifications. According to the classification proposed by Hanna et al. [22], the appropriate technique for fibrous dysplasia treatment is suprastructure maxillectomy. However, according to the criteria proposed by Spiro et al. [23], the appropriate technique is subtotal maxillectomy. The purpose of open surgery for maxillectomy is to remove the tumor by resecting the maxillary wall involved.

Brown et al. [25] suggested the classification of post-maxillectomy defects with the aim of facilitating reconstruction and guiding the clinician through the process. Bidra et al. [24] conducted a literature review of the classification proposed by Brown et al. The review yielded positive results because the classification divides the types of defects into vertical and horizontal types. The patient in this case report was classified as having a type V vertical defect because she suffered from left-sided facial defects covering the anterior maxillary wall, medial maxillary wall, and inferior orbital rhyme. She also suffered from left eye enophthalmus, which led to the occurrence of orbitomaxillary defects after suprastructure maxillectomy.

The orbitomaxillary defect is caused by attachment of the tumor to the maxilla and tissue around the orbit. The tissues surrounding the nose, maxilla, and orbit are elevated when suprastructure maxillectomy is performed. Suborbicularis fat, orbital retaining ligaments, and part of the orbital base are lifted after maxillectomy, which leads to enophthalmus. Reconstruction is aimed at not only closing the defect but also restoring the function and aesthetics of the face. Therefore, expertise and caution are necessary for good results. The use of mesh plates in post-maxillectomy reconstruction is in accordance with the study by Zhang et al. [26], in which a titanium mesh was used during reconstruction on post-maxillectomy patients with orbital floor defects.

Titanium materials are widely used in reconstruction, not only in the maxillofacial region but also through the body. Titanium is an alloplastic substance that is biocompatible and causes minimal allergic reactions due to the calcium-like chemical composition. The material achieves good integration with bone without causing fibrosis as described by Schubert et al. [27].

The patient described here was treated using a modified titanium mesh plate and muscle sling. Modification of management techniques following reconstruction is sometimes necessary to close the occurring defect. A muscle sling was employed to provide resistance and replace the orbital hanging ligaments, preventing enophthalmus. Reconstruction continued with the installation of titanium mesh as the orbital base while simultaneously

reconstructing the anterior maxillary wall defect to obtain a shape that resembles the wall. The medial maxillary wall defect was reconstructed using a plate to keep the eyeball stable and to form the construction of the lateral nasal wall. The management process for this reconstruction is consistent with the reports by Zhang et al. [26], Lv et al. [29], and Motiee-Langroudi et al. [28] with a little modification to use muscle slings as orbital anchors. The final step involved suturing by observing the aesthetic contours of the face according to the facial fat compartment as described by Prendergast et al. [12].

Central Jakarta, Indonesia

ABSTRACT

Cleft palate is a congenital abnormality of the face, in which the palate does not develop normally during pregnancy. It is caused by failure of the fusion of the lateral palatine procesuss, resulting in the persistence of a slit-like opening between the oral and nasal cavities. Velopharyngeal insufficiency is the inability of the velopharyngeal valve to close owing to a deficit in the velopharyngeal structure, and one of the causes is cleft palate. The activities of swallowing and speaking depend on the ability to achieve adequate closure of the velopharyngeal valve. Here we present a 21-year-old man with cleft palate since birth. He had complaints of nasal sounds (rhinolalia) and water/food coming out from the nose every time he swallowed. He underwent surgery to correct this abnormality. Cleft palate closure was performed using the V-Y pushback technique and a posterior pharyngeal flap as this approach can extend the palate and effectively improve speech function. After the surgery, there were no disruptions in eating and drinking, and the patient spoke more clearly and was satisfied. A good understanding of the anatomy, physiology, and pathophysiology of cleft palate is very important for the appropriate management in order to achieve optimal and comprehensive treatment with regard to all aspects of aesthetics, speech, and swallowing ability.

Keywords: Congenital abnormalities, cleft palate, velopharyngeal insufficiency

INTRODUCTION

Cleft palate is a congenital abnormality of the face, in which the palate does not develop normally during pregnancy. It is caused by failure of the fusion of the lateral palatine processes, resulting in the persistence of a slit-like opening between the oral and nasal cavities [1]. Cleft palate is more common in males than females. Additionally, it is more common in Asians (1–2.1/1000 births) than Africans (0.41/1000 births). The etiology of cleft palate is multifactorial. Genetic factors are involved in about 25% of patients with a family history of cleft palate; therefore, the chance is even greater for a future child to be born with a cleft. Environmental factors, such as drug consumption during pregnancy, infection during the first trimester of pregnancy, alcohol consumption, and vitamin deficiency, also contribute to cleft palate [1, 2, 3].

Velopharyngeal insufficiency is the inability of the velopharyngeal valve to close owing to a deficit in the velopharyngeal structure, and one of the causes is cleft palate. The activities of swallowing and speaking depend on the ability to achieve adequate closure of the velopharyngeal valve [4]. Treatment for these abnormalities includes surgery and a complete team approach to help with the multiple complications that can occur in such a case. Here, we present a man with cleft palate who had speech issues. Cleft palate closure was performed using the V-Y pushback technique and a posterior pharyngeal flap. This technique was selected because it can extend the palate and improve speech function [5-6].

CASE REPORT

A 21-year-old man with cleft palate since birth presented with a complaint of nasal sounds (Figure 1A). He also mentioned that water/food came out from the nose every time he swallowed. He had never been treated, as he was not disturbed by the abnormality. However, when he started working, he experienced problems communicating with his coworkers and supervisor. In July 2018, he underwent cleft palate surgery using the V-Y pushback technique. After surgery, he could speak more clearly, although there were still nasal sounds (Figure 1B). After 2 months postoperatively, a small fistula (around 3 mm in diameter) was noted in the surgical area (Figure 1C). Thus, in October 2018, he underwent revision surgery using the V-Y pushback technique and a posterior pharyngeal flap (Figure 2A, B). After the surgery, there were no disruptions in eating and drinking, and he could speak more clearly and was satisfied. In January 2019 (3 months after the revision surgery), he underwent speech assessment, including the mirror test (Figure 3) and kutugajah test to evaluate nasal air emission. He could not correctly pronounce the nasal consonants. There was dew on the mirror; however, he could not correctly pronounce the letters k, i, q, c, j, z, r, d, a, and s. Speech therapy was planned. He was trained several times to pronounce the nasal consonants, and a palatometer was used. Further evaluation is planned 1 month later.

DISCUSSION

In patients with cleft palate, one of the problems is speech function/communication [5]. Our patient with cleft palate underwent surgery using the V-Y pushback technique and a posterior pharyngeal flap, as this approach can extend the palate and improve speech function well [6-9]. In this case, the patient underwent alaroplasty in adulthood, which is usually performed at the age of 10–18 months. Subsequently, the patient received speech therapy to improve nasal air emission and training to pronounce the nasal consonants [10]. In our center, most patients with cleft palate undergo an audiological examination, and if the results are within normal limits, a nasometric examination is performed. Then, palatoplasty is performed, and after 1 month postoperatively, nasometry/ nasopharyn-goscopy is performed to evaluate the velopharyngeal valve and assess the presence of speech disorder.

Figure 1. Cleft palate appearance. (A) Before surgery; (B) 3 days after surgery; and (C) 2 months after surgery.

Figure 2. Cleft palate appearance after revision surgery. (A) Fourteen days after revision and (B) 2 months after revision.

Figure 3. Mirror test.

CONCLUSION

In patients with cleft palate, speech function should be examined before and after palatoplasty. Cleft palate is a congenital disorder often found in the social community. A good understanding of the anatomy, physiology, and pathophysiology of cleft palate is very important for appropriate management in order to achieve optimal and comprehensive treatment with regard to all aspects of aesthetics, speech, and swallowing ability.

TONGUE EDEMA AFTER PALATOPLASTY: A CASE REPORT

Rahendra*, Pradini

Department of Anesthesiology and Intensive Care, Faculty of Medicine,
Universitas Indonesia and Cipto Mangunkusumo National Central Hospital,
Jakarta, Indonesia

ABSTRACT

Palatoplasty is a commonly performed procedure in children. A complication of palatoplasty is tongue edema owing to the use of a mouth gag. Tongue edema can compromise the airway and be dangerous for the patient. The objective of this case report was to increase awareness that tongue edema may arise after palatoplasty and to explain how to manage it. We present the case of a 17-month-old female who presented with tongue edema after palatoplasty. Massive tongue swelling developed 2 hours post-surgery. The patient showed signs of upper airway obstruction and was reintubated. The patient was under observation in the intensive care unit for three days until the tongue size returned to the original. A longer observation period in the recovery room after surgery may be required to prevent occurrence of hazardous events after palatoplasty.

Keywords: tongue edema, palatoplasty, airway obstruction

INTRODUCTION

Palatoschisis is a frequently occurring congenital craniofacial disorder. The Centers for Disease Control and Prevention (CDC) has estimated that 2.650 babies are born every year with palatoschisis in the United States [1, 2]. Palatoschisis can cause swallowing, talking, and breathing disorders in sufferers. Palatoplasty needs to be performed to correct this disorder and is typically performed at the age of 9-18 months. Corrections performed in palatoplasty

* Corresponding Author's Email: rahend2k@yahoo.com.

include repair procedures in the hard palate and mole palate. Almost all palatoplasty procedures involve the use of a mouth gag to separate the tongue and cheeks from the surgery area, making it easier for the surgeon to access the operating area [1, 3, 4].

Although the use of a mouth gag in this procedure has been shown to ease surgery, there are many reports of complications arising from suppressing mouth gags to surrounding structures [2, 5, 6]. A complication that arises owing to the suppression of mouth gag is edema of the tongue. Although rare, edema of the tongue can cause upper airway obstruction, which, if not treated properly, has the potential to be life threatening [7-9]. This case report aimed to discuss the management of patients who develop post-palatoplasty tongue edema.

CASE REPORT

A healthy 17-month-old, 10-kg female was scheduled for palatoplasty. The patient had labiopalatoschisis since birth and had undergone surgery for labioschisis at the age of 6 months. Based on the patient's history and examination, there were no complaints or abnormalities other than palatoschisis. She was assessed as ASA 2 with congenital anomaly (palatoschisis). In the operating room, anesthesia was induced by using sevoflurane 8%, which was titrated down to 2.5%. A 24-G infusion line was secured in the patient's left hand. Fentanyl 2.5 mcg/kg (25 mcg) and atracurium 0.5 mg/kg (5 mg) were administered to facilitate intubation. Intubation was performed using direct laryngoscopy, with endotracheal tube size 4 (non-kinking type), fixed at 12 cm. The cuff was not inflated owing to pediatric airway consideration. A throat pack was inserted by the anesthesiologist. The ventilator setting was VC (Volume Control) 80/4/20/40%. No difficulties were faced while performing intubation.

After intubation, the patient's head was placed in a hyperextended position. A mouth gag was inserted by the surgeon. During the surgery, the surgeon changed the mouth gag position several times and increased the pressure because the visualization of the operating field was difficult. However, hemodynamically, the patient was stable with an estimated total blood loss of 50 mL. The surgery lasted for 3.5 hours. Anesthesia was maintained with administration of 2%-2.5% sevoflurane in air with 45% oxygen. At the end of surgery, the throat pack was removed, and the surgeon stitched a palatum pack to block unanticipated bleeding from the surgical site.

Figure 1. Intraoperative Position. (A) After intubation. (B) After mouth gag insertion.

Figure 2. Tongue swelling. (A) More massive tongue swelling 2 hours post-surgery. (B) Decreased tongue swelling 3 days post-surgery.

At the end of the procedure, the residual neuromuscular block was antagonized, spontaneous ventilation was assessed to be adequate, and extubation was performed. Soon after extubation, the patient showed labored breathing with intercostal retraction. Oxygen saturation decreased to 88%; 100% oxygen was administered via the face mask, but the saturation continued to decrease until 76%. Propofol (25 mg) was injected to sedate the patient, and an LMA was inserted to provide adequate ventilation.

Soon after insertion of LMA, oxygen saturation increased to 100%. The anesthesiologist decided to wait until the effect of propofol subsided. Naloxone 0.01 mg/kg (0.1 mg) was added to reverse any residual opioid. The decision to exert the LMA was made after the patient gained consciousness and spontaneous ventilation was adequate. However, soon after LMA exertion, the patient showed labored breathing with intercostal retraction again, and oxygen saturation decreased to 90%. An oropharyngeal airway sized 0 was inserted, which solved the issue. Oxygen saturation quickly increased to 100%. A quick re-evaluation of the patient's airway was done, and a mild lingual edema was found. The anesthesiologist asked the surgeon to remove the palatum pack, so that air could flow through the oral cavity despite the presence of mild lingual edema. The child could then breathe normally without a period of desaturation. It was decided that the patient would be observed for longer period of time in the recovery room.

Two hours post-surgery, the patient developed a more massive lingual edema and produced a stridor sound, indicative of an impending airway obstruction. The decision to re-intubate the patient was made; reintubation was extremely difficult and was performed within two attempts using C-MAC and bougie. Soon after the intubation, an emergency lingual exploration was performed by the surgeon, which found no bleeding, hematoma, or laceration on the tongue. The patient was transferred to the intensive care unit (ICU) for observation. Dexamethasone was injected daily to reduce tongue swelling. After a 72-h in ICU, the tongue size slowly returned to normal. The patient was then extubated.

DISCUSSION

Airway compromise following palatoplasty may be owing to tongue swelling, laryngeal edema, pharyngeal secretions, blood clots, a retained throat pack, prolonged action of anesthetic agents, or a combination of factors [1, 2, 5, 9]. Tongue swelling is an unusual sequel to cleft palate repair. Ischemia induced by the pressure arising from prolonged use of a mouth gag results in necrosis of the tongue muscle, venous stasis, and lymphedema, resulting in lingual swelling, which indicates tongue ischemia with reperfusion hyperemia and capillary leakage as important mechanisms [3, 4]. Hyperextension of the head may also contribute to an impaired blood flow to the tongue, producing more lingual venous stasis and swelling, necessitating immediate reintubation, which may be extremely difficult [2, 5, 6].

The onset of tongue edema can be insidious over a 2–2.5-h period [3, 8, 9]. This is potentially dangerous because by then, the patient is likely to have been discharged to the general ward. Tongue examination prior to extubation is needed after every palatoplasty surgery. It is important to maintain airway patency until the tongue size returns to normal.

CONCLUSION

Massive tongue swelling can compromise the airway. Periodic release of the mouth gag during palatoplasty prevents prolonged ischemia to the tongue. Once lingual edema develops, it is important to maintain airway patency until the tongue size returns to normal. It is important to keep in mind that reintubation is often difficult. A longer observation may be required especially in an ambulatory setting to prevent a hazardous event.

ABSTRACT

Facial clefts are extremely rare congenital anomalies. There are various types of clefts, and classifications are required for their description. Nasal anomalies are rare and, currently, there are no standard methods for the management of such defects. The number of operations and types of surgical intervention vary widely according to the pattern and complexity of the deformity. The aim of this case report is to formulate a standardized procedure for there pair of the nasal component of Tessier no. 3 clefts. A nasal dorsum advanced rotational flap was used to close the cleft of ala nasi during the first-stage surgery. Second-stage surgery involved an osteotomy and septoplasty to obtain a better shape for the nasal dorsum. During the third operation, we reconstructed the ala nasi to obtain improved symmetry. The nasal dorsum rotation flap showed good healing over the lateral surface of the nose and in the subciliary region. The closure of the nasal defect was accomplished using a composite downward rotation flap of the ala based on the lateral cleft wall. An advanced rotation-transposition flap was used in the management of a Tessier no 3cleft. We also recommend the use of a superiorly based transposition for extensive lateral nasal wall involvement. In the present case, we performed osteotomy and septoplasty to obtain an improved shape for the nasal dorsum. Although the symmetry between the two nostrils was not ideal, it was acceptable.

Keywords: Tessier no. 3 cleft, advanced rotation-transposition flap

INTRODUCTION

Facial clefts are extremely rare congenital anomalies. There are numerous variations and classifications of clefting. The cleft nasal deformity is mostly associated with cleft lip and palate [1]. The goals of cleft nasal surgery are to re-establish normal nasal tip projection and align the nares and the position of the nasal base. Various techniques have been considered to repair these defects [1, 2].

A facial cleft is an opening or gap in the face, or a malformation of a part of the face. Nasal deformity involves the skin, cartilage, mucosa, and skeletal platform [1, 2]. Fortunately, congenital clefts of the nose, whether isolated or associated with other craniofacial clefts, are rare. The exact incidence remains unknown. The incidence of craniofacial clefts, other than cleft lip and palate, is reported to be 1.4–4.9 cases per 100,000 live births. Even among these cases, a cleft of the nose is rare [3]. Several studies reported that congenital nasal anomalies are rare, with an incidence of one case per 20,000–40,000 livebirths [4]. Nasal anomalies are rarely observed, which may account for the diagnosis and treatment plans that result in a less than satisfactory outcome. Nasal defects are also part of craniofacial clefts and other various well-documented syndromes.

Several theories have been proposed to explain the etiology of facial clefts. At present, an established theory is the mesodermal penetration theory, which states that clefts occur along potential lines of fusion due to the lack of mesodermal penetration. Without this reinforcement, epithelial breakdown and separation may occur [4].

Facial clefts have been classified according to their pathology, etiology, pathomorphology, topographic anatomy, and time of development. The most commonly used classification for craniofacial clefts is the Tessier classification, proposed by Paul Tessier in 1976 [1]. This classification is based on specific axes (0–14) along the face and the cranium. The orbit divides the cranial clefts (9–14) from facial clefts (0–7), and facial clefts have cranial extensions. Tessier clefts involving the nose are types 0, 1, 2, and 3 with their cranial counterparts. The patterns of nasal clefts are variable, ranging from simple notch or asymmetry of the alar margin to complex complete craniofacial cleft involving the lip, nose, eyelid, brow, forehead, and underlying bones [1, 5, 6].

CASE PRESENTATION

We present an 18-year-old female with a Tessier no. 3 facial cleft. She did not have a history of nasal obstruction or cyanosis at birth. The patient had an isolated unilateral cleft of the left ala nasi, without other congenital abnormalities (Figure 1).

Computed tomography showed only deformities on the mucosa of the ala nasi, without cartilage deformities. Deviation of the nasal septum was observed. However, there were no structural defects of the hard tissue (Figure 2).

Figure 1. A female patient with a left Tessier no. 3 cleft. (A. Anterior view, B. Right lateral view, C. Right oblique view, D. Left lateral view, E. Left oblique view, F. Basal view).

Figure 2. Computed tomography findings showed no abnormality in bone structure.

In this study, we used an advanced rotational local flap for the management of the patient. The incision design was made to obtain an improved symmetry and remove unnecessary structures. We set three reconstructive goals (i.e., reconstruction of the alar rim without a discernible notch, achieving symmetry with the normal side, and closing the secondary defect using local tissues).

The open rhinoplasty approach was performed to locate congenitally deformed anatomical landmarks, especially the cartilaginous framework of the nose. Nasal dorsum advanced rotational flaps were literally based from advanced rotation flaps. This flap design was in the shape of a pattern using ala from the other side. The medial incision was superficial, and a dissection was performed subcutaneously toward the nasomaxillary suture area. A deep dissection was continued lateral to the nasomaxillary suture area to mobilize the flap.

Open rhinoplasty was performed to open the anterior nasal area. This process exposed the alar cartilages. The lateral crura of the affected alar cartilage were dissected away from the nasal mucosa. The lining of the nasal mucosal was stretched and attached anteriorly to close the cleft. The lateral crus of the affected alar cartilage was repositioned laterally to be contiguous with the lateral crus of the lower lateral cartilage. The pedicled skin flap was rotated downward to recreate the alar rim. However, the limitation of this approach was that the flap was unable to rotate too far away to prevent the flap to stretch away and also to make sure the flap got good vascular feeding. (Figure 3). We inserted a nasal tampon to fixate the flap for 3 days.

A follow-up examination performed 1 month after surgery indicated that the flap was in good condition. However, it required additional intervention to obtain an improved ala symmetry. Second-stage surgery (refinement) was performed 7 months after the first-stage surgery.

Figure 3. First-stage surgery. (A. Design of incision was to obtain symmetry). (B-E. Superficial and deep dissection and open rhinoplasty of the Nasal dorsum rotational flaps for correction of Tessier no. 3 facial cleft) (F. Removal of unneeded cartilage and mucosa). (G. Closure of the nasal dorsum rotational flaps for correction of Tessier no. 3 facial cleft).

Figure 4. Second-stage surgery. (A. Marking of dorsum and ala nasi incision). (B-E. Undermined ala nasi and removed unneeded structure) (F. Superior view of second stage surgery shows a good shape of dome and ala nasi).

During second-stage surgery, osteotomy was performed to undermine the mucosal segment of the nasal dorsum. We used septoplasty to recreate the ala. In addition, we undermined the ala nasi to reconstruct the dome of ala nasi and obtain an improved shape and good symmetry. Although the symmetry between the two nostrils was not ideal, it was acceptable. Multiple procedures were performed to ensure a good healing process of the graft and closure of the secondary defect (Figure 4).

The results of the nasal dorsum rotation flap showed good healing over the lateral surface of the nose and in the subciliary region. However, scarring over the alar cartilage was suboptimal. The closure of the nasal defect was accomplished using a composite downward rotation flap of the ala based on the lateral cleft wall (Figure 5). The main defects were closures using advanced nasal dorsum rotational flap, while the secondary defect is closed after assessment of tissue availability and the remaining scars. Multiple approaches were performed to obtain an improved shape and symmetry of both nostrils.

Figure 5. Anterior and lateral views prior to surgery (A and D), and 1 month after surgery (B and E) and 2 months (C and F) after second-stage surgery.

DISCUSSION

Paul Tessier studied facial clefts, and his clinical classification has become the current international standard. The cleft crosses the nasal ala between the tail of the alar cartilage and the alar base, and the tip [1]. The most distinguishing characteristics of the Tessier no. 3 facial clefts are: medial orbital maxillary clefts, characterized by displacement of the medial canthus, superior displacement of the ala nasi cleft lip, alveolus and palate, coloboma of the lower eyelid, nasolacrimal abnormalities, disruption of the medial wall of the antrum, a cleft in the medial wall of the orbit, and teleorbitism.

Considering the rarity and lack of standard guidelines, the management of patients with such facial clefts is challenging. Depending on the degree of malformation, a staged procedure is currently considered the treatment of choice. However, various surgical protocols have been described in the literature, and the selection of approach has not been standardized [3]. The Australian Craniofacial Unit Treatment Protocol, which is one of the most widely accepted protocols for the management of facial clefts, has suggested early repair of the soft tissue defects and prevention of exposure keratitis. In addition, the protocol states that bone grafting if needed, orthognathic surgery, and rhinoplasty may be performed after the patient reaches adulthood. Moreover, this protocol propounded the role of tissue expansion in the cheek to accommodate bone grafts. Numerous different types of flaps may be used to repair such lateral defects of the nose, depending on the size, shape, and site of the defects [3].

The main surgical goal in the treatment of patients with Tessier no. 3 clefts is nasal symmetry, which is rarely achieved. Surgeons have proposed different techniques for the repair of Tessier no. 3 facial clefts. Madaree et al. [7] used five local flaps, with two pairs

utilizing the “z” plasty principle to achieve lengthening and the fifth being a turnover flap for additional nasal lining. A full thickness flap of the alar rim was rotated downward, thereby equalizing the external nares. The medially based turnover flap was used to close the gap. Monasterio et al. [8] used a local transposition flap to correct skin shortening between the medial canthus and the eye. A medial flap was rotated to elevate the dystopic canthus, and cheek flaps were advanced to close the gap and lengthen the nose [9, 10].

In the present case, we found that this flap improved alarsymmetry; however, it decreased the nostril area. The main limitation of this technique is the notch in the affected ala that required multiple corrective procedures. Similar results were obtained by Monasterio et al. [8]. These investigators suggested the need for multiple refining procedures and claimed that severe clefts extending along the whole length may be corrected by rotation of longer nasal flaps alone or in combination with forehead flaps.

CONCLUSION

We recommend the use of the advanced rotation-transposition flap for the management of nasal defects associated with Tessier no 3 clefts. We also recommend the use of a superiorly based transposition for cases with extensive lateral nasal wall involvement. In our case, we performed osteotomy and septoplasty to obtain an improved shape for the nasal dorsum. Surgeons may infrequently observe such cases. Consequently, they may not possess the necessary expertise to individualize the corrective procedure. The present technique is simple and can be easily incorporated in the armamentarium of surgeons. A number of studies reported that several surgical procedures are required to obtain an improved shape and nasal symmetry. In the present case, three procedures were performed to achieve acceptable symmetry between the two nostrils.

ABSTRACT

Limb salvage surgery with tumor resection and endoprosthesis insertion is currently the preferred treatment for malignancies of the extremity. However, this procedure is not feasible in many cases and requires expensive implants that may not be available or affordable for many patients, such as in developing countries. We present three cases with distinct malignancies of the knee, osteosarcoma, metastatic bone disease due to lung cancer, and spindle cell carcinoma, treated by resection arthrodesis. After wide excision of the tumor, the combination of plates crews and K-nails with bone cement was used for arthrodesis. Functional outcomes were evaluated using the Lower Extremity Functional Scale (LEFS) score. LEFS scores were 24, 30, and 26 out of 80, respectively. These low scores reflected substantial loss of limb immobility. Resection arthrodesis is a viable treatment option for limb salvage in cases of knee tumor for which resection and endoprosthesis insertion are not feasible, but functional outcome is limited.

Keywords: limb salvage, resection arthrodesis, functional outcome

INTRODUCTION

Musculoskeletal tumors are relatively rare, accounting for less than 1% of all malignancies [1]. However, the majority of lower extremity tumors affect the knee, a critical

* Corresponding Author's Email: adisayr@gmail.com.

joint for full limb function. Wide resection is reserved for a small subset of patients with biologically more aggressive, recurrent, and extensive tumors. Wide resection and mobile joint reconstruction are preferable for treating tumors around the knee. In certain situations, resection arthrodesis or amputation is suggested. Limb salvage surgery with tumor resection and endoprosthesis insertion is the preferred treatment, but the expensive implants may be unattainable, especially in developing countries. Resection arthrodesis is currently considered a less attractive option due to loss of joint mobility. However, resection arthrodesis does provide a stable limb, and the patient is unlikely to require revision surgery [2, 3]. In this case series, we examined the outcomes of resection arthrodesis for three distinct knee malignancies.

CASE SERIES

The first case (Table 1) was a 15-year-old male who reported pain in his left leg for 18 months before presentation (Figure 1). The patient was diagnosed with osteosarcoma and referred to CiptoMangunkusumo Hospital, where he received four cycles of neoadjuvant chemotherapy before limb salvage surgery with wide excision and ELIAS cancer immune therapy in January 2016 (Figure 2). The wound became infected, however, requiring two corrective surgeries, but neither was successful. In May 2016, the cement was exposed. The patient then underwent knee arthrodesis in December 2016. The postoperative outcome as measured by LEFS score was 24 out of 80, indicating substantial disability (Figure 3).

The second case was a 60-year-old male who reported left leg pain for the past year before presentation. There was no history of trauma or prolonged fever, although he reported a history of weight loss. There was progressive swelling of his left knee (Figure 1). The patient was diagnosed with lung cancer in 2014 and had received curettage and bone cement surgery in December 2015. Pathological examination revealed micro-metastases of adenocarcinoma. Three months later, pain re-emerged in the same region, and X-ray examination confirmed metastatic bone disease of the left distal femur (Figure 2). In October 2016, the patient underwent limb salvage surgery using resection arthrodesis. Postoperative LEFS score was 30 (Figure 3).

The third case was a 16-year-old male who reported pain in his right knee, starting six months before presentation. His knee was swollen and painful, although he could still stand and walk (Figure 1). The patient received three treatments from a bonesetter. Two months later, a nascent lump on the knee had enlarged to the size of a tennis ball. The growth was painful and firm. In April 2016, the patient received a core biopsy, and histopathological examination revealed conventional osteosarcoma (Figure 2). At that time, the lump had grown to the size of a volleyball with no clear margin; was painful, firm, with solid consistency; and felt warmer than the surrounding tissue. The patient then decided to receive neoadjuvant chemotherapy for three cycles with a regimen of cisplatin, ifosfamide, and adriamycin. After finishing chemotherapy, the lump was still expanding, although no inflammation or ulceration was noted. The patient agreed to limb salvage surgery including wide excision and reconstruction using right knee arthrodesis. Postoperative LEFS score was 26 (Figure 3).

Table 1. Summary of patient information

Patient	Diagnosis	Location of lesion	Time from initial complaint to arthrodesis	Other treatments	Postoperative LEFS score
Male, 15 y	Osteosarcoma	Left leg	16 months (August 2015–December 2016)	4 cycles of neoadjuvant chemotherapy Wide excision and ECI ¹ Debridement and implant removal	24
Male, 60 y	Metastatic bone disease from lung carcinoma	Left thigh	2 years (2014–2016)	Chemotherapy for lung carcinoma Curettage and bone cement application	30
Male, 16 y	Osteosarcoma	Right knee	Approximately 1 year (2015–2016)	Neoadjuvant chemotherapy by cisplatin, ifosfamide, and adriamycin	26

y: year, ECI: ELIAS cancer immunotherapy.

Figure 2. Preoperative X-ray images of the first, second, and third patients (from left to right).

Figure 3. Postoperative X-ray images of the first, second, and third patients (from left to right).

DISCUSSION

The primary goals of knee tumor excision are to prevent recurrence and prolong life, which generally requires wide-margin resection, whereas functional preservation or restoration is secondary [4]. The choice of reconstruction strategy after resection of a tumor around the knee joint is based on many factors. Arthrodesis provides stable, durable, and predictable reconstruction that preserves some leg motion but at the expense of flexion and extension at the knee. Once the decision has been made to perform arthrodesis, the specific technique selected should have demonstrated success with few complications, as this group of patients will probably receive postoperative chemotherapy and some will have limited life expectancy [5].

Enneking and Shirley [6] proposed the following indications for resection arthrodesis: 1) a recurrent benign, potentially malignant, or malignant lesion that involves the distal end of the femur, the knee joint, or the proximal end of the tibia; 2) a tumor location with an adequate plane of uninvolved tissue between the lesion and posterior neurovascular structures for surgical resection according to the degree of aggressiveness of the tumor; and 3) a vigorous patient whose expectations and lifestyle require a stable, painless extremity capable of withstanding demanding function. All three of our cases were deemed suitable for resection arthrodesis based on these criteria [6].

Kwan [7] evaluated the outcomes and complications associated with resection arthrodesis for 22 primary bone tumors (13 giant cell tumors and nine osteosarcomas) around the knee and reported that of 14 patients who returned for final evaluation, 79.8% had satisfactory outcomes according to the Musculoskeletal Tumor Society grading system. A study by Alam [8] evaluating functional outcomes in children with a malignant tumor around the knee joint also supported the efficacy of resection arthrodesis, particularly for pediatric sarcomas around the knee and for cases in which endoprosthesis insertion is not feasible because of young age or lack of resources. In a study by Bassiony et al. [9], all patients receiving resection arthrodesis achieved functional results comparable with endoprosthetic patients. This result was confirmed by Harris et al. [10], who reported that patients functioned similarly and walked with comparable velocities, efficiencies, and oxygen consumption rates whether treated by arthrodesis or arthroplasty.

In our cases, the outcome was measured using the LEFS, which consists of 20 items evaluating the ability to perform everyday tasks, each with a maximum score of 4[11] The LEFS results in our cases indicated substantial functional limitations after arthrodesis. Nonetheless, resection arthrodesis appears preferable to amputation. Shih et al. [12] reported a 5-year survival rate of 39% following arthrodesis for knee osteosarcoma, which was lower than following endoprosthetic insertion (60%) but higher than after amputation (13%).

CONCLUSION

Resection arthrodesis is a viable treatment option for limb salvage in patients with tumors around the knee, although the functional outcome is limited. However, for cases in which prosthesis replacement is unobtainable, arthrodesis with wide excision still salvages a tumorless limb with some functional capacity.

ABSTRACT

Chordoma is a low-to-intermediate-grade malignant tumor encapsulating the notochord. It is rare, insidious in onset, and frequently diagnosed late. Due to its size, location, and nature, surgical treatment becomes challenging. Here we report a case of sacral chordoma in a 33-year-old woman treated with a combined anterior and posterior approach to remove the tumor enbloc, followed by posterior stabilization using rod-screw system. Total sacrectomy and spinopelvic reconstruction is the treatment of choice for sacral chordoma. We were able to achieve complete resection of the tumor mass with no recurrence after six months of follow-up.

Keywords: sacrum, chordoma, combined posterior and anterior approach, sacrectomy

INTRODUCTION

Chordoma is a low-to-intermediate-grade malignant tumor encapsulating the notochord. It accounts for 1%–4% of all primary malignant bone tumors, is insidious in onset, and frequently has a late presentation. Most chordomas present after the age of 30, with one-third occurring in the sixth decade [1]. This is a slow-growing but locally aggressive tumor and

* Corresponding Author's Email: risky.wisnubaroto@gmail.com.

originates from primitive notochordal elements. This tumor is mainly found along the midline from the base of the skull to the sacrococcygeal region of the pelvis [2].

The treatment goal for sacral chordoma is to achieve en bloc excision with tumor-free margins to maximize local tumor control and survival. However, this is challenging in some cases, as sacral chordomas are difficult to excise entirely because preservation of sacral stability and sacral nerve pathways to the rectum and bladder limits the extent of the surgery [2, 3]. The prognosis for these patients correlated with negative surgical margins, which almost always results in a poor prognosis in patients with intralesional resection [2, 4].

We report a case of sacral chordoma in a 33-year-old woman presenting with radiating pain and bladder obstruction as the primary symptoms. Due to the nature of the tumor involvement, we performed an en bloc sacral resection with the Galveston technique using a combined anterior and posterior approach, achieving stability with pedicle screw and rod fixation.

CASE REPORT

A 33-year-old female patient presented to our office with a chief complaint of ongoing pain in her left hip for four years. The symptoms started with periodic cramps in the hip that radiated to her feet. Though the pain was initially abated with the use of over-the-counter pain killers, some degree of pain remained. Approximately two years ago, the patient started experiencing lower urinary tract symptoms along with worsening hip pain, which had now extended to her left knee. She consulted with an internist and was diagnosed with a urinary tract infection and treated accordingly. However, shortly after that, she was unable to pass urine and was eventually hospitalized. A complete workup was performed, including a CT scan, which revealed an abdominal mass. She was referred to an obstetrician-gynecologist, and a working diagnosis of uterine myoma was made. A follow-up MRI was performed, which showed the bony origin of the tumor. Next, the patient was referred to our outpatient clinic for treatment at CiptoMangunkusumo Hospital.

Figure 1. Lateral and anteroposterior view of the sacrum. No remarkable features were noted during the physical examination.

No remarkable features were noted during the physical examination. Examination of the lower back revealed no palpable mass, minimal tenderness of the lower back with palpation, and a visual analog scale score of 2–3. Also, she had a normal range of motion of the hip,

knee, and ankle joints. Neurological examination revealed a sensory deficit in the left lower extremity, particularly the lateral aspect of the foot, along with hypoesthesia in the perianal region. Motor examination of the lower extremity identified slight weakness of the gastrocnemius and peroneus muscles of the left foot (motor score 4/5). In addition, the patient exhibited catheter dependency of the bladder with normal bowel function.

We conducted a pelvic X-ray and an MRI of the whole abdomen and the lumbosacral area. From the plain radiograph of the pelvis, we identified a mass extending to the right sacroiliac joint (S1–S5) that was suggestive of a chordoma.

Figure 2. Anteroposterior and lateral view of the pelvis. The mass extends from S1 to S5, with possible involvement at the right sacroiliac joint.

Next, we obtained an MRI of the lower abdominal and pelvic region, which revealed a dense, lobulated mass with active hemorrhage from S1 to S5, extending to the anterior and posterior, obliterating the anterior visceral organs and spinal cord, respectively, suggestive of chordoma. The mass also appeared to involve the sacrum, the Coccygeus, and part of the left iliac ostium.

A follow-up was done with a CT-guided biopsy of the lesion. The pathology results matched the initial suspicion of the diagnosis, with features characteristic of a chordoma.

From the medical history, physical examination, imaging, pathologic examination, and conferences with a range of specialists, we diagnosed the tumor as sacral chordoma. Surgery is the treatment of choice; thus, the orthopedic and spinal oncology teams performed total sacrectomy and spinopelvic reconstruction, respectively.

We elected to divide the operation into two stages. For the first stage, the tumor was resected, and posterior instrumentation of the cervical spine was performed. For the second stage, pelvic reconstruction with fibular graft was performed in hopes that the patient can sit independently.

In the first stage of the operation using an anterior approach, we made a midline incision along the abdomen to remove the anterior part of the tumor, incising the rectus abdominis and the internal and external oblique muscles. There, we obtained a view of the tumor, which was putting pressure anteriorly on the intraperitoneal organs. Next, we released the anterior mass of the tumor, whereas the vascular team performed ligation of the internal iliac and median sacral arteries. The gastroenterology team preserved the sigmoid colon, created the stoma,

and closed the wound. We prepared the patient in pronation to remove as much of the tumor as possible to ensure a clear margin.

Figure 3. MRI of the lumbar spine and pelvic region demonstrating the extent of the lesion. (a) Sagittal view showing involvement at L5–S5 and obliteration of the spinal canal. (b) AP view showing the lesion extending to both sacroiliac joints and involving the gluteus minimus and medius muscles.

For the second stage of the operation, we continued the posterior approach to release the posterior portion of the tumor and remove the sacrum and the tumor mass. A longitudinal incision was made through the midline of the sacrum from L2 to the coccyx. The tumor mass extended to the bilateral S1 joints. We removed the tumor and a small amount of the surrounding tissue. The L2–L5 nerve roots were compressed within the tumor mass.

To stabilize the site, we installed pedicle screws at the L2–L4 level, and at the bilateral sacroiliac joint (Galveston technique). We performed laminectomy between L5 and S1 and ligation of the thecal sac, followed by an osteotomy at L5–S1. We removed the tumor and placed the fibular bone allografts. Finally, we closed the wound and installed a closed-suction drain.

Figure 4. Posterior view of the chordoma extending from S1 to S5. Note the presence of nerve roots within the mass.

Figure 5. (a) gross view of the chordoma. (b) The cross-sectional view of the tumor. Note the lobulated mass with fat lobules separated by fibrous bands.

Figure 6. (a) Direct view of the screws. The allograft used to promote bone healing is not shown. (b) Anteroposterior view of the hip post-operation. (c) Anteroposterior and lateral view of the hip post-operation.

The tumor mass was sent for pathological evaluation. The results were consistent with chordoma, macroscopically, and also microscopically, with the appearance of lobulated cell mass separated by fibrous bands. Besides, the presence of “physaliphorous cells” (pale vacuolated cytoplasm) suggested a chordoma.

DISCUSSION

The clinical features of a chordoma correlate with the location and spread of the neoplasm. As this is a slow-growing tumor, it usually produces characteristic signs and symptoms, making diagnosis difficult. Pain in the sacrococcygeal region is the most common presenting symptom. The pain is dull and may be felt on the lower back or the tip of the spinal column. Constipation or anuria may be experienced due to the obstruction [1]. The degree of obstruction in the patient made her dependent on the catheter until the time of surgery.

Currently, surgery is still the mainstay of treatment for sacral chordomas. Enbloc excision remains the central tenet in the surgical management of chordoma [5]. Kaiser et al. reported that local recurrence was almost twice as high in patients who underwent en bloc resection with dissection of the tumor capsule at the time of surgery compared with those who had complete en bloc excision without violating the tumor capsule [6]. Today, more aggressive surgery and wider surgical margins have improved the local control of sacral chordomas [7].

Before the operation, we talked to the patient about all of the possible consequences of the operation, including recurrence, reoperations, and diminished functional outcomes [8]. We also acted quickly before the tumor occupied more space in the pelvic area, and before more symptoms occurred and became a further risk to the patient.

For this patient, we used a combined anterior and posterior approach due to the extensive nature of the tumor. This approach is used only for tumors with radiological suspicion of anterior involvement. In most cases, chordomas are extremely difficult to excise completely [9]. A combined anterior and posterior procedure allows for an intralesional/marginal resection of the tumor and the involved vertebra. En bloc resection of primary malignant bone tumors, including chordoma, is shown to increase the survival rate of patients and is a crucial part of the treatment regimen [3].

The extent of sacral resection determines pelvic stability and the need to undergo reconstruction. We performed an osteotomy at L5–S1 and removed the tumor involving the S1 joints. Such a procedure may cause spinopelvic dissociation, resulting in gross instability in the rotational and vertical planes. Therefore, reconstruction and reinforcement are needed to ensure stability [10]. We placed iliac screws and screws at L2–L3–L4 to maintain stability.

Even though our patient received meticulous care, there were some complications. The patient developed a fever with pain at the surgical site. The allografts were identified as the primary cause of infection; thus, we debrided the wound and removed the graft. Also, despite our best efforts at prevention, early signs of decubitus ulcer (bed sore) were noted on the left buttock.

The complication rate after total sacrectomy is quite high, mainly related to wound healing. A second or even third surgery may be required to remove deep wound infection or flap necrosis [11]. Postoperatively, the patient retained her neurological status and experienced less pain. There was no recurrence of the tumor after six months of follow-up.

CONCLUSION

Chordoma is a rare primary bone tumor. Clinicians of different specialties need to recognize these conditions early, as the symptoms are not characteristic and are site-dependent — adequate surgical treatment results in substantial improvement in neurological function and symptoms. Extensive tumor removal using a combined anterior and posterior approach followed by a stable reconstruction may achieve a favorable clinical outcome [3]. Even with strict adherence to protocol, the risk of infection is high, and a second operation may be required [4, 9, 10].

ABSTRACT

Introduction: Dural scarring may develop after laminectomy, resulting in persistent back and leg pain. Laminectomy for decompression exposes the dura mater, stimulating the growth of scar tissue on the dural surface. Such scarring can impair nerve conduction and induce chronic pain, localized according to the affected spinal levels. *Case Presentation:* A single case of back pain and pain radiating to the lower limbs is reported 12 months following laminectomy at L4–L5. Magnetic resonance images revealed new soft tissue in the posterior region pressing on the dura. *Discussion:* Re-operation was performed for decompression. Intraoperative examination revealed scar tissue around the dural surface at the previous laminectomy site. Decompression and scarctomy were conducted, but the outcome was unsatisfactory because it proved impossible to remove all the scar tissue from the dura without increasing the risk of nerve root damage. As a result, low back pain was mitigated, but the leg pain persisted. *Conclusion:* Laminectomy can result in dural scar formation and chronic pain that is intractable to reparative

surgery. Thus, it is critical to institute perioperative procedures that reduce the risk of subsequent dural scar formation.

Keywords: Dura scar, laminectomy, leg pain, fibrosis

INTRODUCTION

Postoperative dural scar formation, involving the paravertebral musculature, thecal sac, and nerve roots, is a frequent cause of recurrent symptoms and pain after lumbar disk surgery [1, 2]. Such dural lesions result from the destruction of epidural fat, intra-spinal hematoma, and advancement of the spinal erector muscles into the spinal canal, [3] and are a major cause of lumbar pain and sciatic irritation after lumbar surgery. The mechanical tethering of nerve roots to the dura by epidural adhesions may contribute to persistent back and leg pain after lumbar laminectomy, termed failed back syndrome [4, 5].

Non-invasive treatments are being developed to reduce neural adhesion to scar tissue. Absorbable, oxidized, regenerated cellulose (Inter-ceed) reduced neural adhesion in a rabbit model following experimental laminectomy [6]. In addition, intraoperative neuromonitoring (IONM) can predict the risks of adverse outcomes, such as paraparesis, paraplegia, and quadriplegia, following spinal surgery [7]. Nonetheless, prevention and treatment of dural scar formation remain substantial challenges for spinal surgeons.

We report a case of dural scar following laminectomy that resulted in progressively worsening low back and radiating leg pain. This case highlights potential complications that should be anticipated before primary surgery and re-operation for scar excision, including preventing a dural tear, as well as the importance of IONM.

CASE ILLUSTRATION

A 36-year-old male with no history of spinal trauma presented with complaints of worsening back pain, radiating to the right and left legs, for the previous two months. It was described as continuous sharp pain with intermittent tingling that was influenced by activity and disappeared in the resting position. He had reported back pain four years earlier, described as dull intermittent pain without spread or tingling, which was treated using pain relievers and physiotherapy. Two years before the current presentation, he reported back pain and was examined by a neurosurgeon, who diagnosed lumbar disc herniation at L4–L5 and performed fenestration and laminectomy. The patient reported being pain free until the previous two months, when he began to experience back pain in the same place. He also suffered weakness during dorsiflexion. An orthopedic spine surgeon recommended reparative surgery after conducting a full examination. The patient provided informed consent to publish anonymized clinical results.

At presentation, lumbosacral MRI showed compression of the right thecal sac and nerve roots caused by right posteroparacentral protrusion of L4 and L5 intervertebral discs (Figure 1). There was also a hyperintensity region on the posterior side of the L3–L5 intervertebral discs from suspected scar tissue. A myelograph revealed mild spinal canal indentation at the

same level as intervertebral discs L4 and L5, which was diagnosed as lumbar canal stenosis due to disk herniation and scar formation (Figure 2).

Figure 1. Preoperative MRI. (a) Sagittal projection showing disk protrusion at the L4–L5 level and a hyperintense defect posterior to L3–L5. (b) Axial projection showing canal stenosis and inflammation of facet joints and flavum ligaments.

Surgery was performed, using the posterior approach, at L4–L5. Scar tissue was attached to the entire dural surface field, measuring about 1.5 cm² and extending to the edge of the lamina. After pedicle screw fixation (Figure 3), we attempted to free the dural surface of scar tissue. Unfortunately, this proved impossible, so we performed a partial scarectomy and carefully created a floating dura (Figure 4). After surgery, pain symptoms were reduced, sensorimotor functions were normal, and the patient was able to return to his normal activities. However, leg pain persisted during follow-up.

Figure 2. Myelograph showing mild indentation of the spinal canal at the level of intervertebral discs L4 and L5.

Figure 3. Intraoperative findings. (a) Posterior stabilization with pedicle screw fixation. (b) Exposed dural scar at spinal level L4–L5.

Figure 4. Postoperative X-ray (anteroposterolateral projection). Pedicle screw stabilization at spinal levels L4, L5, and S1.

DISCUSSION

Scar formation around the dura and the nerve root may cause clinically intractable complications following laminectomy. Post-laminectomy scar tissue is formed mainly by invasive fibrous connective tissue from the posterior paraspinal muscles into the postoperative hematoma [6]. Connective tissue from the bony edges of the laminectomy margins may also contribute to a limited extent. Scar tissue invasion into the vertebral canal is suppressed when epidural fatty tissue is present. Even if absent, invasion of scar tissue into the vertebral canal is not very marked. However, the scar tissue may adhere strongly to the dura. Therefore, separating the postoperative hematoma from vertebral canal tissues, including the dura, may inhibit scar tissue from invading the vertebral canal and adhering to the dura [2]. The current case underscores the importance of preventing scar formation in the perioperative period. Intraoperative neuromonitoring is critical for this purpose.

Monitoring during structural spine and spinal cord surgeries may include somatosensory evoked potentials (SSEP), motor evoked potentials (MEP), and electromyography (EMG, free running and stimulated) [8]. MEP directly monitors the motor pathway itself. The persistence of full muscle MEP amplitude usually indicates good central motor function preservation, while substantially reduced MEPs or elevated thresholds can indicate partial, transient, or even permanent central motor deficits. It is currently difficult to explain these different outcomes following MEP reduction. Partial weakness can be difficult to assess in the acute postoperative patient and so may be overlooked, while documented weakness may recover slowly. Thus, long-term evaluation is critical for identifying intraoperative MEP signs of more severe and lasting damage. Note, however, that a partial central motor deficit is possible even without any appreciable intraoperative muscle MEP alteration [8]. Somatosensory

evoked potentials (SSEP) are generated by stimulation of afferent peripheral nerve fibers by electrical, vibrational, or tactile stimuli. Following either mixed nerve or sensory nerve stimulation, SSEPs can be recorded over more proximal portions of the peripheral and central nervous system, including the peripheral nerves, spinal cord, and/or brain [7].

CONCLUSION

A dural scar is a fibrotic lesion that can form after laminectomy and cause recurrence of back pain and (or) radiating leg pain. Scarring is favored by factors such as the fibrous organization of hematomas, keloid reaction, and technical faults in the operation, and may develop into a hypertrophic, enveloping membrane. Pain severity and distribution depends on the dural scar's size and location. Attempts to limit tissue formation involve surgical technique variations, microdissection, anti-inflammatory medications, and several biologic and synthetic materials. However, preventing epidural fibrosis after laminectomy remains a major challenge in spinal surgery.

ABSTRACT

Kyphotic deformity is a devastating complication of spondylitis tuberculosis as it can progress to more severe complications, such as cardiopulmonary dysfunction and nerve compression symptoms. Surgical correction is as important as local infection control itself (through debridement and abscess drainage). There are several approaches for spondylitis tuberculosis with kyphotic deformity, and all are based on the patient's condition and other local considerations, such as hospital and national health policies. This report aims to provide information on the clinical and radiological outcomes after two-stage treatment for kyphotic deformity in patients with spondylitis tuberculosis. We present four cases of kyphotic deformity in patients with spondylitis tuberculosis who underwent two-stage surgery at Cipto Mangunkusumo National Hospital, Jakarta, Indonesia. All patients were female, with a mean age of 37.5 years. The mean follow-up period was 45 months. One patient had a lumbar lesion with loss of lordosis (less than 20° lordosis), and the remaining three had thoracic lesions with a kyphotic angle more than 45°. All patients underwent a two-stage surgery involving initial debridement, kyphotic correction, posterior stabilization, and fusion, followed by anterior fusion with a titanium cage and bone graft. The surgical outcomes were evaluated by comparing the preoperative and postoperative Oswestry Disability Index (ODI) scores and kyphotic angles. After surgery, all patients had good outcomes with reductions in the ODI score and kyphotic angle. The mean ODI score reduced from 20 preoperatively to 5

* Corresponding Author's Email: abay.jabz@gmail.com; First author.

postoperatively. Additionally, the kyphotic angle reduced from 90° preoperatively to 22° postoperatively (after the second stage). Our two-stage procedure for the treatment of spondylitis tuberculosis with kyphotic deformity was associated with good functional and radiological outcomes at long-term follow-up. Thus, we recommend this two-stage procedure as a standard for cases similar to our reported cases.

Keywords: anterior fusion, kyphotic deformity, posterior stabilization, spondylitis tuberculosis

INTRODUCTION

Indonesia has the third highest tuberculosis (TB) endemicity, and spinal TB is quite common, although the exact prevalence of spondylitis tuberculosis (STB) in Indonesia is unclear [1]. The major problems associated with this disease are pain and deformity. Kyphotic deformity has been reported as a disabling complication of spinal infection, as progression causes additional pain, cardiopulmonary symptoms, and possible neurological deficit, in addition to the cosmetic problem itself [2].

Surgical debridement and stabilization are considered in many patients with progressive deformity and abscess formation with or without neurological deficit. Stabilization for deformity correction and maintenance can be achieved either with bone grafts alone or with a combination of grafts and posterior or anterior instrumentation [3].

Implant placement in an infected area remains controversial, partly because it is unclear whether implants interfere with infection control. This has led many authors to treat STB in two stages with initial debridement and bone grafting followed by delayed instrumented fusion. Although approach selection for the surgical treatment of thoracolumbar TB is still being debated, a combined anterior plus posterior approach can help overcome the stability-related drawbacks of the anterior approach alone. However, this approach entails two surgeries (single or staged) with additional morbidity [3].

This report aims to provide information on the clinical and radiological outcomes after two-stage treatment for kyphotic deformity in thoracic and thoracolumbar TB at our center. We present four cases of kyphotic deformity in STB patients who underwent first-stage debridement and decompression followed by second-stage anterior fusion with a titanium mesh cage and graft.

CASE SERIES

Between 2011 and 2016, 15 patients with confirmed STB infection (nine females and six males; mean age, 34.3 years; age range, 13–65 years) were treated surgically with a two-stage procedure involving debridement, kyphotic correction, and stabilization followed by anterior fusion at Cipto Mangunkusumo National Hospital, Jakarta, Indonesia. However, 11 patients were lost to follow-up, and thus, we were able to collect data from only four patients. All four patients were female, and the mean age was 37.5 years. Of these four patients, one had lumbar loss of lordosis and the other three had kyphotic deformity.

In the first stage, we performed debridement, kyphotic correction, and stabilization. All patients were operated under general anesthesia and were placed in the prone position. A posterior midline approach was used in all patients. Debridement was performed by removing necrotic material within the body and disk by using curettes, and any paraspinal abscess was drained. Kyphotic correction was achieved by inserting bilateral pedicle screws at 2–3 cranial and caudal vertebrae. Further correction was achieved after completion of rod insertion by gradual compression between the screws toward the apex of the deformity. Finally, posterolateral fusion was performed by trimming the facets and laminae of the diseased vertebral segments. The bone materials obtained in the trimming process were used as bone grafts.

In the second stage, we performed anterior fusion by the anterior approach. All patients were operated under general anesthesia and were placed in the supine position. Thoracotomy was performed, and then, anterior reconstruction of the vertebral body was performed using a titanium mesh or anterior cage filled with cancellous bone grafts from the iliac spine.

Before surgery and after the first and second stages, we evaluated the kyphotic angle using Subroto Angle Aid (Figure 1 and 2). Subjectively, we determined the disability level using the Oswestry Disability Index (ODI) questionnaire before surgery and at follow-up (more than 6 months) (Figure 3). The ODI questionnaire includes questions that assess a patient's ability to perform activities of daily living.

Figure 1. Radiography in patient 1. (a) Preoperative regional kyphotic angle, 96°; (b) Kyphotic angle after the second stage, 24°; (c) Kyphotic angle at a 4-year follow-up, 28°.

- Rasa nyeri menghalangi saya mengangkat beban berat tetapi saya dapat mengangkat beban yang ringan sampai tak berat bila diperlukan di tempat yang cocok untuk saya. (Nilai 3)
- Saya hanya mampu mengangkat beban yang sangat ringan. (Nilai 4)
- Saya tidak mampu mengangkat atau membawa apapun. (Nilai 5)

Bagian 4: Berjalan

- Rasa nyeri tidak menghalangi saya untuk berjalan sejauh apapun. (Nilai 0)
- Rasa nyeri menghalangi saya berjalan lebih dari 1 mil. (Nilai 1)
- Rasa nyeri menghalangi saya berjalan lebih dari 0.5 mil. (Nilai 2)
- Rasa nyeri menghalangi saya berjalan lebih dari 0.25 mil. (Nilai 3)
- Saya hanya dapat berjalan dengan bantuan tongkat atau alat perantara. (Nilai 4)
- Saya hampir selalu berbaring di tempat tidur dan hanya bergerak ke toilet. (Nilai 5)

Bagian 5: Duduk

- Saya dapat duduk di kursi apapun selama yang saya inginkan. (Nilai 0)
- Saya hanya dapat duduk di kursi kasur karena saya takut jatuh. (Nilai 1)
- Rasa nyeri menghalangi saya duduk lebih dari 1 jam. (Nilai 2)
- Rasa nyeri menghalangi saya duduk lebih dari setengah jam. (Nilai 3)
- Rasa nyeri menghalangi saya duduk lebih dari 10 menit. (Nilai 4)
- Rasa nyeri membuat saya tidak dapat duduk sama sekali. (Nilai 5)

Bagian 6: Berdiri

- Saya dapat berdiri selama yang saya inginkan tanpa menambah rasa nyeri. (Nilai 0)
- Saya dapat berdiri selama yang saya inginkan tetapi menambah rasa nyeri. (Nilai 1)
- Rasa nyeri membuat saya tidak mampu berdiri lebih dari 1 jam. (Nilai 2)

Bagian 7: Tidur

- Rasa nyeri tidak menghalangi saya tidur dengan nyaman. (Nilai 0)
- Saya hanya dapat tidur nyenyak dengan minum obat. (Nilai 1)
- Sekali minum obat, saya tetap tidak dapat tidur lebih dari 6 jam. (Nilai 2)
- Sekali minum obat, saya tetap tidak dapat tidur lebih dari 4 jam. (Nilai 3)
- Sekali minum obat, saya tetap tidak dapat tidur lebih dari 2 jam. (Nilai 4)
- Rasa nyeri membuat saya tidak dapat tidur sama sekali. (Nilai 5)

Bagian 8: Hubungan seks

- Hubungan seks saya berlangsung secara normal dan tidak menambah rasa nyeri. (Nilai 0)
- Hubungan seks saya berlangsung secara normal tetapi agak menambah rasa nyeri. (Nilai 1)
- Hubungan seks saya berlangsung hampir normal tetapi sangat menyakitkan. (Nilai 2)
- Hubungan seks saya sangat terbatas karena rasa nyeri. (Nilai 3)
- Saya jarang sekali berhubungan seks karena rasa nyeri. (Nilai 4)
- Saya tidak pernah berhubungan seks karena rasa nyeri. (Nilai 5)

Bagian 9: Kehidupan sosial

- Kehidupan sosial saya berjalan secara normal dan tidak menambah rasa nyeri. (Nilai 0)
- Kehidupan sosial saya berjalan secara normal tetapi menambah rasa nyeri. (Nilai 1)
- Rasa nyeri tidak banyak berpengaruh pada kehidupan sosial saya selain membuat saya ragu yang membatasi aktivitas fisik seperti berenang. (Nilai 2)
- Rasa nyeri membatasi aktivitas sosial saya dan saya agak jarang bergengsi. (Nilai 3)
- Rasa nyeri membatasi aktivitas sosial saya dan saya agak jarang bergengsi. (Nilai 4)
- Saya tidak terlibat dalam kehidupan sosial karena rasa nyeri. (Nilai 5)

Bagian 10: Menghindari perjalanan

- Saya dapat melakukan perjalanan ke mana saja tanpa menambah rasa nyeri. (Nilai 0)
- Saya dapat melakukan perjalanan ke mana saja tetapi menambah rasa nyeri. (Nilai 1)
- Saya dapat melakukan perjalanan selama lebih dari 2 jam tetapi ini mengakibatkan rasa nyeri cukup parah. (Nilai 2)
- Rasa nyeri menghalangi saya untuk melakukan perjalanan selama lebih dari 1 jam. (Nilai 3)
- Rasa nyeri menghalangi saya untuk melakukan perjalanan selama lebih dari 30 menit. (Nilai 4)
- Rasa nyeri menghalangi saya untuk melakukan perjalanan kecuali untuk pergi ke dokter atau rumah sakit. (Nilai 5)

Skor IDI: jumlah nilai / 50 x 100 = _____ / 50 x 100 = _____ %

Interpretasi:

- 0% - 20% Ketidakmampuan minimal
- 21% - 40% Ketidakmampuan moderat
- 41% - 60% Ketidakmampuan berat
- 61% - 80% Umpan
- 81% - 100% Pasien tidak dapat bangun dari tempat tidur

Figure 5. Oswestry Disability Index scale (in Bahasa).

The mean follow-up period was 45 months. All patients reported a better condition postoperatively. The mean preoperative ODI score was 20 (patients 1, 2, 3, and 4: 16, 22, 24, and 18, respectively), and the mean postoperative ODI score was 5 (patients 1, 2, 3, and 4: 2, 8, 4, and 6, respectively). The mean kyphotic angle reduced from 90° preoperatively to 30° after the first stage and 22° after the second stage.

DISCUSSION

Indonesia has the third highest TB incidence worldwide, with an incidence of approximately 1,020,000 (30 per 100,000 population). Although the exact incidence and prevalence of STB in most parts of the world are not known, in countries with a high burden of pulmonary TB, the incidence of STB is expected to be proportionately high [1].

STB is a disease of developing countries and is more likely related to the socio-economic status. Unfortunately, its morbidity involves nerve compromise that eventually results in tetraplegia or severe kyphosis, which can affect cardiopulmonary function. Furthermore, this disease mostly affects young adults in their most productive years, and thus, it reduces productivity and triggers a vicious cycle of poverty. Because of these issues, effective and applicable treatments to prevent further morbidity are urgently required.

The main aims of STB treatment are as follows: (i) TB eradication using anti-TB drugs; (ii) general condition improvement; (iii) deformity prevention or correction using decompression and stabilization; and (iv) prevention or treatment of complications, such as neurological deficit.

Chemotherapy is highly effective for controlling tubercular infection. However, patients treated with chemotherapy alone have an average increase in kyphotic deformity of 15°, and 3%–5% of patients develop kyphosis greater than 60°. Severe kyphosis can lead to immense cosmetic and psychological disturbances in growing children and can cause costopelvic impingement, secondary cardiorespiratory problems, and late-onset paraplegia. Correction of established kyphosis is both difficult and hazardous, with a high rate of complications, even when performed by experienced surgeons. Deformity prevention should be an integral part of any treatment schedule for spinal TB [5].

The role of surgery in STB treatment is still controversial. Surgery is indicated when neurological and spinal deformities are progressive (more than $\pm 40^\circ$ of segmental kyphosis, anteroposterior or lateral translation) or when conservative approaches fail to treat the neurological deficit and deformity, severe pain occurs owing to an abscess or spinal instability, and the diagnosis is uncertain (inability to diagnose microbiologically with microscopy, culture, or even polymerase chain reaction for the detection of mycobacterial DNA) [3, 5, 6].

Deformity prevention should be the primary aim in the treatment of spinal TB, as the availability of potent anti-tuberculous drugs has made uncomplicated TB a medical disease. The severity of deformity in spinal TB depends on the extent of vertebral destruction, level of the lesion, and age of the patient, with more severe deformities seen in children and in patients with lesions involving the thoracolumbar spine [7, 8].

Surgery for established deformity is difficult, and it might need to be staged. Additionally, it is hazardous with a significant complication rate. Even with a staged

approach, Yau et al. reported a mortality rate of 10%, and the mean correction amount was only 28%. They advocated that corrective surgery should be performed only in patients with severe deformity, active disease, or imminent paraplegia or death from chest complications [5, 7, 8].

Refinement of surgical techniques, development of new approaches, and availability of rigid spinal instrumentation have made single-stage correction of established deformity relatively safe with good outcomes. Transpedicular decancellation osteotomy, pedicle subtraction osteotomy, and direct internal kyphectomy have been used to treat kyphosis in active as well as healed diseases. Jain et al. reported kyphosis correction through an extra-pleural, anterolateral (costotransversectomy) approach, with a mean kyphosis correction of 27.3° and no persistent neurological deficit. Bezer et al. used transpedicular decancellation osteotomy to correct post-tuberculous deformity, with no neural complications [7, 9, 10].

The two-stage surgery performed in our center was adjusted according to the National Health Insurance coverage policy. The outcomes regarding reductions in the ODI score and kyphotic angle were good and matched our aim for treating the patients. Thus, we recommend this two-stage procedure as a standard for cases similar to our reported cases.

CONCLUSION

Our two-stage procedure for the treatment of spondylitis tuberculosis with kyphotic deformity was associated with good functional and radiological outcomes at long-term follow-up. Thus, we recommend this two-stage procedure as a standard for cases similar to our reported cases.

ABSTRACT

Conus medullaris syndrome is a complex disease entity that is difficult to define because of its location between the spinal cord and nerve roots. The presenting symptoms are not specific and are often missed by primary doctors, making diagnosis challenging. It is even more difficult because the time since onset plays a major role in the outcome. A 47-year-old female displayed neglected conus medullary syndrome due to a compression fracture of L1 that presented as bladder and defecating dysfunctions and leg pain due to lumbar canal stenosis of L4-L5. A decompression surgical procedure involving total laminectomy at the L1 level, posterior stabilization from T11 to L3, and laminotomy, flavectomy, and discectomy at L4 and L5 were performed in this patient. The patient experienced improved motor function after the operation. Her hypoesthesia also improved. However, her bladder and defecating problem were not resolved. Non-full function restoration likely occurred because of the patient's neglected conus medullaris. However, her function still improved; therefore, surgery was a better option.

INTRODUCTION

The conus medullaris is very susceptible to injury because of its proximity to the commonly injured thoracolumbar junction [1]. Conus medullaris syndrome results in a tremendous burden due to the resultant morbidity, expenses, and resources necessary to treat the disease. This disease affects an estimated 14,000 people in the United States annually [1].

Conus medullaris syndrome is a complex disease entity that is difficult to define because of its location between the spinal cord and nerve roots [2]. This disease manifests itself as back pain, unilateral or bilateral leg pain, weakness or paresthesia, and bladder or bowel incontinence [3]. In thoracolumbar or lumbosacral injuries, conus medullary syndrome should be distinguished from cauda equina syndrome: the latter presents as a spinal cord compression and dysfunction (upper motor neurons) whereas symptoms in the former present as lumbosacral radiculopathies (lower motor neurons) [3]. However, the lesions affecting the transition between the conus medullaris and cauda equina may present symptoms consistent with both upper and lower motor neurons [2, 3]. This research work has been reported in line with the Surgical Case Report criteria [4].

CASE ILLUSTRATION

A 47-year-old female came to the orthopedic clinic with a chief complaint of numbness on both legs and the perianal area that worsened during the month prior to her visit. Five years previously, the patient had fallen from a tree of 2–3 meters in height. She landed in a sitting position. The patient was unable to walk immediately after the fall, and she could not control her urge to urinate or defecate. The patient also felt numbness at the perianal area and the posterior part of both legs. At that time, the patient was still able to move her legs but was reluctant to walk because of back pain. The patient sought treatment at a nearby hospital, and a urinary catheter was inserted, but she was referred for further treatment. The patient continued treatment in the form of massages and was able to walk after 8 months of treatment. After those 8 months, the patient did not continue with the treatment and merely went to a nearby clinic for urinary catheter changes.

After 4 years, the patient went to a nearby hospital for defecation and micturition problems. She was then referred to a larger hospital and was treated by a rehabilitation specialist; however, she was only given analgesics. After 6 months, the patient discontinued treatment. Over the last month, numbness in both calves worsened, accompanied by a tingling sensation.

A physical examination of the spine revealed that there was no wound, deformity, or other evident issues (Figure 1). A neurological examination revealed impairment in sensory and motor function in the S1 region; her motor strength was a 4 (on a scale of 1 to 5), and her sensory function was a 1 (on a scale between 0 and 2). Her patellar (L4) and Achilles (S1) tendon reflexes were normal. Babinsky's reflex and clonus were not present in this patient (Figure 2). Her bulbocavernosus reflex was negative. Additionally, her autonomic nerve function (micturition and defecation control) was disturbed.

Figure 1. Clinical pictures of the patient before treatment.

The laboratory investigation results were unremarkable except for the increased erythrocyte sedimentation rate. A lumbosacral x-ray showed a thoracolumbar kyphotic deformity, osteophyte, loss of height, and sclerotic endplate at the first lumbar vertebrae, and good bone stock, accompanied by narrowed disc space in T12–L1 and L1–L2 (Figure 3). A magnetic resonance imaging (MRI) of the lumbosacral spine showed a compression fracture of the L1 vertebrae with suppression on the conus medullaris and myelopathy at the T12–L1 level. Spondyloarthrosis lumbar with a herniated nucleus pulposus at L2–L3 until L4–5 and nerve root compression at the L3–L4 and L4–L5 levels was also observed (Figure 4).

Figure 2. Neurologic examination showing sensory impairment at the S1 level.

Figure 3. X-ray of the lumbosacral spine: (a) posteroanterior projection and (b) lateral projection.

Figure 4. MRI of the lumbar spine. (a) T2-T1 sagittal projection shows a fracture at vertebrae L1. (b) Axial projection shows the fracture line and narrowing of the canal at that level.

Based on her history, physical examination, and laboratory and radiologic investigations, the patient was diagnosed with neglected conus medullaris syndrome due to a compression fracture of L1 and leg pain due to lumbar canal stenosis of L4–L5. We had already performed a decompressive surgical procedure consisting of total laminectomy at the L1 vertebrae, posterior stabilization from T11 to L3, and laminotomy, flavectomy, and discectomy at L4 and L5. The surgery lasted three hours. The somatosensory evoked potential and motoric evoked potential were monitored throughout the surgery.

Her postoperative results showed improvement in both sensory and motor functions. In the lower extremities, both sensory function and motor strength at the S1 level increased to 2 and 5, respectively. Her neurological examination showed that the patella and Achilles tendon reflexes were unimpaired. Babinsky's reflex and clonus were still not present. However, the patient still complained of micturition and defecation, similar to the preoperative state.

DISCUSSION

Diagnostics

This patient presented to our clinic with symptoms and signs suggestive of conus medullaris syndrome. The findings from her history and physical examinations were supported by x-ray and MRI examinations that revealed compression at the level of the conus medullaris. However, the patient also presented with leg numbness, which is not consistent with conus medullaris syndrome. The MRI then showed lumbar canal stenosis at the L4 and L5 vertebrae, which is consistent with leg pain. These two clinical entities are seldom found in one patient, which makes this a unique case.

Because the two disorders appeared in one patient, we decided to perform decompression and stabilization for L1 (where the conus medullaris syndrome originated) and only decompression for L4–L5 (where the LCS appeared). Before the surgery, the patient was classified as Frankel D, which improved to Frankel E after the surgery. This is consistent with findings from Rahimi–Moghavar in which all patients classified as Frankel D improved to Frankel E after surgery [5].

Surgical Intervention

We elected to perform a laminectomy using a posterior approach to release the conus medullaris of the L1 from compression. The segment was stabilized using screws and rods (Figure 5). Despite being decompressed, the fourth and fifth lumbar vertebrae were not stabilized because intraoperatively, we determined that the segment was still stable. Neurological deficit and instability were the main indications for surgery, as stated in the literature. Posterior decompression, followed by an instrumentation two levels above and below the injury level are the most common surgical procedures performed [5]. The posterior approach provides excellent visualization and access to the dorsal sac, which is useful for the treatment of the concomitant fracture. The entrapped nerve root compression cannot be accessed through an anterior approach [2].

Figure 5. Intraoperative procedure. (a) Exposure; (b) pedicle screw placement and laminectomy of L1; (c) and (d) laminotomy, flavectomy, and discectomy of L4–L5; (e) final instrumentation; (f) X-ray of thoracolumbar post op Ap Lat.

The results of a timely surgical procedure have not been established in patients with conus medullaris syndrome [6-9]. Immediate surgery has been associated with excessive bleeding, which has prompted surgeons to delay treatment for 2 to 3 days; however, this has not yielded significant differences in outcomes. Notably, in conus medullaris syndrome, the decision to perform immediate surgery does not correlate with better results compared with delayed surgery [8-10]. Therefore, the recommendation is to perform surgery within three days of injury to achieve a better prognosis with immediate decompression reserved for those with a progressive neurological deficit with significant thecal sac compression. However, currently, no studies have reported the outcome of surgery performed 5 years after the injury.

This report indicates that even after 5 years, surgery for conus medullaris syndrome still results in improvement in sensory and motor functions [6-8].

Neurologic Impairment

Even after surgery, our patient still complained of poor bladder and bowel function. The results from another study also showed that bladder function displayed the least improvement compared with motor or sensory function. Transfeldt reported that although neurologic improvement occurred in 68% of patients who underwent surgery within 2 years, only 27% of patients reported improvement in bladder function. Although these lesions often have a devastating effect on the quality of life, they do not significantly shorten the lifespan [6-8, 11]. A good outcome was recorded if there was a recovery of one or more motor-root levels in the lower extremities or partial recovery of multiple levels. A fair result was recorded if there was a partial improvement of one or two motor-root levels, and a poor result was shown by no cord or root improvement; however, it would be adequately significant if the case was acute to compare the result, which was difficult to apply to our patient [11, 12]. Further workup and management is necessary to assess the bladder and defecating problems of patients. Several treatment options are available, but rehabilitation therapy is the mainstay of treatment. Currently, stem-cell based regenerative medicine is gaining popularity for spinal cord injuries because it may benefit patients; however, this option has several issues still at stake that must be resolved [13, 14].

CONCLUSION

The management of conus medullaris syndrome includes decompression of the spinal cord level that is injured and providing stability for the structure. Diagnosis is challenging, and management is even more difficult for patients because of its associated complications, particularly when neglected. We presented a case of conus medullaris syndrome due to a neglected compression fracture that coincidentally co-existed with lumbar canal stenosis. Surgery was the elected option, and it improved motoric functions, although the bladder and defecating function results were not satisfactory. Stem-cell-based therapy might benefit the latter problem.

CONFLICT OF INTEREST

The authors declare that there are no conflicts of interest regarding publication of this paper.

INFORMED CONSENT

The authors have obtained consent from the patient.

ABSTRACT

Congenital malformations in bladder and cloacal exstrophy involve the genitourinary tract, musculoskeletal tissue, and occasionally the gastrointestinal tract. Pediatric orthopedists and urological surgeons need to have substantial knowledge in order to properly manage such cases. The foremost goal of orthopedic reconstruction is to reduce pelvic diastasis, which enables closure of the bladder and abdominal wall, while reducing tension. Here, we report two cases of a seven-year-old boy and a 12-year old boy who were referred to our pediatric surgery service with the diagnosis of bladder exstrophy. Preoperatively, the pubic diastasis of the two patients was 6 and 9 cm, respectively. Bilateral anterior innominate osteotomy with external fixator placement was executed by the pediatric urological surgical team following bladder closure. Both patients remained hospitalized for two weeks on bed rest. Skin traction was not applied. External fixators were applied for eight weeks. Immediately after surgery, the diastases were reduced to 4 cm in the 7-year-old patient and 6 cm in the 12-year-old patient. No postoperative complications occurred in either patient and both were able to walk with normal gaits.

* Corresponding Author's Email: aryadi.paedortho@gmail.com.

Slight external leg rotation was noted. Urological abnormalities were improved. Despite the technique, it is difficult to achieve perfect closure of the pelvic diastasis in this age group. Pelvic osteotomy remains the most beneficial intervention for corrective exstrophy closure. The bilateral anterior technique is recommended for this procedure and is applicable in neglected cases. Further follow-up is needed to evaluate the effectiveness of this technique.

Keywords: pelvic osteotomy, bladder exstrophy

INTRODUCTION

Classic bladder exstrophy (CBE) is a congenital defect primarily involving the musculoskeletal system and genitourinary tract with an incidence of one case for every 10,000–50,000 live births. The intricacy of congenital malformations, which involves bladder and cloacal exstrophy, involves the genitourinary and musculoskeletal systems, and occasionally the gastrointestinal tract. Correct management of these conditions requires sufficient knowledge of pediatric orthopedists and pediatric urological surgeons. The most significant defect of this congenital malformation is cloacal exstrophy, or CBE with additional intestinal prolapse at the site of bladder exstrophy. In some cases, cloacal exstrophy is accompanied by lipomeningocele or myelomeningocele formation and other congenital malformations, such as anal atresia, colonic hypoplasia, genitalia anomalies, and omphalocele development [1–3].

The mechanism of CBE originates from a defect during embryologic development of the abdominal wall. The genetic and environmental origins of this defect remain unclear, although both are considered contributors. It is now hypothesized that throughout the initial embryonic period, the urogenital part of the cloacal membrane fails to regress caudally consequent to the abnormal caudad position of genital tubercles primordia. The urogenital part of the cloacal membrane fails to ventrally migrate and is displaced anteriorly against the abdominal wall. This position prevents migration of the mesenchyme to the midline of the lower abdominal wall, resulting in a shortage of mesenchyme-derived tissues in this area. Following cloacal membrane rupture to shape the urogenital and anal orifices according to the physiological sequence of embryologic events produces herniation of the viscera of the lower abdomen against the lower abdominal wall, which leads to numerous signs of the epispadias-exstrophy complex, as elaborated earlier [4, 5].

The usage of pelvic osteotomy for the reconstruction of bladder exstrophy deformities has been considerably debated over the past several years. Fundamental descriptive analysis of the bony pelvis and deficiencies and deformities of the muscular pelvic floor in patients with exstrophy have resulted in a better understanding of how reconfiguration of the pelvic ring could provide safe and dependable bladder posterior urethra placement within the pelvis. Over the past 20 years, surgery for bladder exstrophy management has progressed significantly, along with the development of different techniques to acquire good closure and optimal functional outcomes. The ultimate goal of orthopedic reconstruction is to reduce pelvic diastasis, thus allowing for closure of the bladder and abdominal walls, while lessening tension [3, 5, 6].

Here, we report two cases of neglected bladder exstrophy and the outcomes of pelvic osteotomy for exstrophy bladder repair with one-year follow-up. To the best of our knowledge, this is the first case series about the management of pubic diastasis in so-called neglected cases of bladder exstrophy.

CASE 1

Our first patient was a seven-year-old boy who was referred to our Orthopedic Pediatric Surgery Department for repair of anomphalocele and bladder exstrophy (Figure 1a) with a preoperative pubic diastasis size of 6cm (Figure 1b). Bilateral anterior pelvic osteotomy in the supine position was performed in August 2017. Salter osteotomy was performed, during which an oblique inguinal incision was made to the ilium and the innominate bone was bared by separation of the periosteum on each side. The posterior limit of the exposure was the sacroiliac joint and the inferior limit was the pectineal tubercle. The sciatic notch was distinctly recognized and an oblique osteotomy was executed with a saw from the iliac crest to the greater sciatic notch, while evading the sacroiliac joint. The oblique osteotomy resulted in adequate bone for placing external fixator pins into the distal and proximal pelvic segments without invasion of the sacroiliac joint. A number of four parallel 4-mm Shanz screws were subsequently inserted into the distal and proximal pelvic segments. The same procedure was completed on the contralateral side. Repair of the bladder and abdominal soft tissue was later accomplished by the urology team. Next, to complete the repair and reconstruction of the bladder, the fixator pins were connected and compressed using a triangular anterior fragment frame to reduce the diastasis (Figure 1c). An X-ray was obtained intraoperatively to confirm the reduction. No wires were used for fixation of the pubic symphysis.

Figure 1. (a) Patient with bladder exstrophy and omphalocele; (b) initially with 6 cm of pubic diastasis; (c) bilateral anterior pelvic osteotomy was performed with external fixation; (d) after surgery, the diastasis was reduced to 4 cm.

Diastasis reduction to 4cm was accomplished immediately in the post-operative period (Figure1d). The patient was bed-rested in the hospital for one week without traction. An external fixator was applied for a total of eight weeks. There were no complications and the patient was able to walk with a normal gait and without any external leg rotation. The urological status of the patient was improved.

CASE 2

Our second patient was a 12-year-old boy who was referred for epispadia correction and pelvic osteotomy. Cloacal exstrophy closure had been completed at another facility (Figure 2a). The patient had a preoperative pubic diastasis of 9cm (Figure 2b). Bilateral anterior pelvic placement with external fixators was performed in October 2017 using a previously described technique, following cloaca closure and repair procedure but parallel to epispadiarepair (Figure 2b). Diastasis reduction to 6 cm was accomplished immediately during the postoperative period (Figure 2d). The patient was hospitalized for two weeks with bed rest but no skin traction. An external fixator was applied for eight weeks. Urological status was improved and no postoperative complications were recorded. Preoperative external rotation of the patient's gait was marginally corrected at postoperative assessment.

Figure 2. (a) Patient with bladder exstrophy that was performed at another hospital; (b) initial pubic diastasis was 9 cm; (c) bilateral anterior pelvic osteotomy with external fixation; (d) reduced the diastasis to 6 cm after surgery.

DISCUSSION

Despite its rarity, pediatric orthopedists should be familiar with bladder exstrophy so that proper treatment can be performed alongside urological or pediatric surgeons. Our institution

has been conducting follow-up examinations of referred cases such as these. We concluded that pelvic osteotomy parallel to closure of a urological defect is significantly advantageous for gait development and prevention of arthrosis of the hip joints. This technique also supports the performance of urological procedures. In most cases, bladder exstrophy is diagnosed in patients younger than five years. These two cases are exceptional and advanced, due to the older ages of the patients upon presentation. These cases presented challenges to determine the best treatment option for diastasis reduction. Bilateral anterior pelvic osteotomy should be performed as soon as possible, but can be applied in older patients for better deformity correction [2–4, 7–11].

The primary objective of early exstrophy repair is closure of the pubic bones and anterior abdominal wall soft tissue while relieving any tension. Any type of osteotomy can avoid dehiscence of the repaired bladder and abdominal wall. There are numerous techniques for pelvic osteotomy available to fit the surgeon's personal experience and preferences. Anterior pelvic osteotomy for children with bladder exstrophy was first described by Frey and Cohen [12] who reported complications in two patients: partial bladder prolapses in one; and a deep wound infection with total breakdown of the reconstruction in a second. Anterior pelvic osteotomy has several benefits, including versatility for both primary and re-do cases without regard to the patient's age; reasonable surgical duration with no positional changes; and limited anesthetic exposure. Blood loss was also minimal, thus blood transfusion was seldom needed [6, 8–11].

The patient is conditioned in the supine position with elevation of the pelvis using a pad. The bladder is isolated with the use of a sterile drape. A 5cm incision is made 1–2cm distal to the anterior superior iliac spine, similar to the incision for Salter osteotomy. The lateral cutaneous nerve of the thigh was identified and protected. Both sides of the pelvis were subperiosteally exposed by the iliac wings to the extent of the sciatic incision, posteriorly to the extent that the medial ligaments of the sacroiliac joint end and caudally just over the triradiate cartilage (Figure 3) [9].

A small window is opened to the periosteum beside the iliac for control during osteotomy and pin insertion. Subsequent to insertion of a Hohmann spacer into the sciatic incision, oblique osteotomy is completed using an osteotome on the iliac. The lower segment of the pelvis afterward should move medially (Figure 4) [2, 3, 5, 12].

One, or occasionally two, fixator pins are inserted into the lower segment of the ilium and one to two pins into the upper segment of the ilium. The incisions are closed with absorbable intradermal sutures, thus making it possible for the pediatric urological surgeon to completely repair the genitourinary tract. Following the urological procedure, closure of the pubic diastasis can be performed in several ways, as determined by the urologist, using nylon 2-0 sutures, while turning the pelvis internally, thus supporting the sutures. In our cases of older patients or those cases of patients with more extreme diastasis, continuously adjusting the external fixator bar may be necessary for gradual closure of the pelvis. For abdominal wall closure, the bars of the external fixator are placed to retain the pelvis in the correct position [1, 7, 13].

We recommend the use of an external fixator for four to eight weeks. The original technique uses skin traction of both legs during fixation in order to avoid early release of the pins. Nevertheless, skin traction was not applied in the present cases because there is no significant benefit in this age group. Radiographic examination should be performed monthly. The pins are to be removed only upon radiographic evidence of consolidation.

Figure 3. Pelvic anatomy in cases of bladder exstrophy.

Figure 4. Pelvic anatomy in cases of bladder exstrophy.

The most common complications of this procedure include infection from the pins, transitory paralysis of the lateral cutaneous nerve of the thigh, and postponement of the consolidation process. Cutaneous traction may also cause complications. Less frequent complications include pseudarthrosis, arthrosis, lower-limb dysmetria, and lesions to the sciatic, femoral, and superior gluteal nerves, while deep infection is a relatively rare complication [10, 12–14].

Sponseller et al. [6] in their study described a new perspective on osteotomy for CBE treatment based on anterior innominate osteotomies performed from 1988 to 1996. The procedure was deemed effective with a postoperative continence rate of 76%. Nevertheless, the degree of pubic diastasis reduction was not significantly associated with continence. These findings suggest that while osteotomy could ensure continence by sling restoration of the pelvic floor muscles surrounding the urethra, the position of the pubic rami offers no significant benefit to achieve continence. It was also discovered that more diastasis correction would be retained during the procedure for older children. As the degree of pubic diastasis increases linearly to growth in patients with untreated CBE, younger patients are more likely to achieve lesser correction as a result of more considerable growth than older patients. When the main objective is to improve the widened perineum in CBE, delay of osteotomy until the age of eight years is recommended in order to achieve an optimal degree of correction [4–7].

CONCLUSION

Further techniques for the repair of bladder exstrophy in older children will be explained in the near future. Nonetheless, pelvic osteotomy is still the most beneficial intervention for the success of corrective exstrophy closure in older children. At present, the bilateral anterior technique is the most recommended for this procedure. However, further follow-up of this technique is needed.

**SUCCESSFUL TREATMENT OF FRACTURE AT THE
BASE OF THE PROXIMAL PHALANX USING EXTRA-
ARTICULAR PERCUTANEOUS K-WIRING WITH THE
CONSIDERATION OF SAFE PORTALS:
A CASE REPORT**

Wahyu Widodo* and Andi Praja Wira Yudha Luthfi

Orthopaedic Hand and Microsurgery, Faculty of Medicine,

ABSTRACT

Fracture of the phalanges can be caused by trauma under various circumstances. Most phalangeal fractures are unstable. The common treatment for unstable phalangeal fractures is Kirschner wire (K-wire) fixation using the most commonly used technique of extra-articular cross-pinning. Using this technique, a stable fracture can be fixed and early phalanx mobilization can be facilitated. To achieve these goals, the landmarks and safe portals for the insertion of the K-wire to the fracture site of the phalanges must be identified. Here we present the case of a 48-year-old woman with fracture at the base of the proximal phalanx of the left fourth finger. For 3 weeks, she underwent closed reduction and immobilization using the K-wire via the extra-articular cross-pinning technique. After 3 weeks of immobilization using the K-wire, no significant events were observed. After removal of the K-wire, we initiated the rehabilitation program. A desirable range of motion (ROM) was achieved at the metacarpophalangeal joint. The safe portals for the insertion of the K-wire for treating proximal phalanx fractures using the cross-pinning technique must be identified to achieve a desirable ROM. Thus, the extra-articular cross-pinning technique along with the safe portals must be used for treating fractures of the proximal phalanges.

INTRODUCTION

Metacarpals and phalanges are the most common sites of fracture in the upper extremity, and such fractures can result from trauma under various circumstances [1]. Emmet and Breck have reported that 10% of 11,000 fractures were metacarpal or phalange fractures. Moreover, Faraqui et al. [2] have shown that fractures at these sites account for 23% of all below-the-elbow fractures in the United States. Proximal phalanx fractures occur more often than middle and distal phalangeal fractures [3]. Phalangeal fractures usually lead to undesirable outcomes because they are frequently neglected or considered insignificant [4].

The treatment of phalangeal fractures is based on several factors, such as location of intra-articular or extra-articular fracture, deformity, pattern of fractures, open or closed fractures, and correlated injuries adjacent to the fracture site. Age, preference of the surgeon, injury mechanism, and occupational need of the patient must also be considered [1, 5]. Treatment of phalangeal fractures, particularly in the extra-articular middle and proximal phalanx, aims to accomplish satisfactory anatomical reduction, maintenance of stability, and early controlled mobilization. Different treatment methods have been presented, which include buddy strapping, closed reduction internal fixation (CRIF) with Kirschner wires (K-wires), splinting, and open reduction internal fixation with plates and/or screws [3, 6].

Despite the availability of novel materials and techniques, the most commonly used tool for stabilization and fixation in phalangeal fractures is the steel pin, which was first introduced by Martin Kirschner in 1909 [7]. In the CRIF method, the safe portals for percutaneous K-wire insertion must be identified for successful treatment. A safe portal is defined as an area where entry of the K-wire will cause minimal soft tissue damage and will not damage major soft tissues, including those in the extensor tendon, nerve, vascular, and flexor tendon, thereby treating pain and promoting active range of motion (ROM).

CASE ILLUSTRATION

A 48-year-old woman was admitted to our emergency department owing to pain and difficulty in moving the metacarpophalangeal (MCP) joint of her left ring finger. Six hours prior to admission, she slipped and fell on the floor, and her body fell on her left hand. She was wearing a ring on her left ring finger at that time. She felt extreme pain on her left ring finger. The patient was right-handed and worked as a nurse. Her general health condition was good, and she did not present with any comorbidities.

Upon examination, swelling and minimal deformity were observed on her left ring finger (Figure 1). Sensation at the distal part was good, and there was no disruption of blood flow to the distal part of the finger. However, she could not move the MCP joint due to extreme pain and swelling.

Based on the radiological findings, an extra-articular fracture was observed at the base of the left proximal phalanx. At the emergency room, we performed closed reduction and immobilized her fingers using ulnar gutter splint and waited for 5 days until swelling in the soft tissue subsided. Treatment with percutaneous K-wiring was recommended, and the risk of joint stiffness and malunion was explained to the patient.

Figure 1. Clinical condition of the left fourth finger.

Figure 2. First radiography image of the left hand showing a fracture with a slight displacement at the base of the fourth finger.

Figure 3. Ulnar gutter splint application was performed in the emergency room.

After 5 days, closed reduction was performed, and we inserted 2 K-wires with extra-articular cross-pinning technique percutaneously under C-arm guidance in the operating room. Regional anesthesia (axillary block) was administered prior to the procedure. First, we flexed the left proximal interphalangeal (PIP) joint of the fourth finger at 90°, and the K-wire was inserted percutaneously, dorsomedially, and dorsolaterally alongside the extensor tendon. Then, C-arm imaging was performed to identify the exact location of the wires. Results showed that the wires were placed properly. The fracture site was stable, and we flexed the MCP joint to ensure that the wire was not placed intra-articularly. The ring and middle fingers were protected with buddy taping, and the patient was discharged from the hospital after the surgery.

Figure 4. Insertion of the K-wire in the operating room. (a) The metacarpophalangeal joint was flexed; and (b) K-wires were inserted percutaneously; (c) After insertion, the tip of the wire was bended to immobilize the wires.

Figure 5. C-arm imaging confirmed the location of the wires in the operating room.

The patient was followed-up in the clinic after 1 week for wound inspection. The K-wire was removed 3 weeks after surgery, and the patient underwent further intensive physiotherapy with active and passive flexion and extension of the PIP joint. She regained full ROM of the MCP joint after 6 weeks. She was then discharged from the outpatient clinic. During follow-up after 3 months, the flexion and extension of the MCP joint were found to be satisfactory, and deformities were not observed.

Figure 6. Range of motion of the metacarpophalangeal joint was assessed after operation by performing flexion (a) and extension (b) to ensure that the wires were inserted extra-articularly.

Figure 7. Range of motion of the metacarpophalangeal (MCP) joint during follow-up after 3 months. Image shows that flexion and extension of the MCP joint were satisfactory, and no deformities were observed.

DISCUSSION

Metacarpal and phalangeal fractures are more commonly observed in men than in women. The incidence is highest in the younger group due to road accidents, sports injuries, and industrial accidents [4]. After reduction of a displaced or unstable proximal phalanx fracture, fixation must be performed with the use of the following implants: K-wires, cerclage wires, screws, plates, tension band wiring, intramedullar devices, external fixator, or staples. The use of the K-wires is the most common fixation method. Such method has several advantages, which include low cost, simple percutaneous application, and minimal disruption of soft tissues, which results in minimal soft tissue damage and preservation of soft tissues and periosteal stability. The removal of pins after fracture healing is not challenging. However, this method also has several disadvantages, which include susceptibility to infections in the pin tract, requirement of additional immobilization over the early healing process, and possible migration of the pin. The K-wires do not offer compression, and they can occasionally distract the fracture site. Although K-wires do not produce rigid fixation, they still provide enough fixation for restricted mobilization. A variety of configurations are commonly used. Each has different degrees of stability. The configurations include crossed-pinning K-wires, parallel K-wires across the fracture site, fixation of intramedullar wire, fixation of transarticular pin or along with wiring to generate a tension band construct, and combination of several types of fixation. The key goal is to achieve stable fixation and early mobilization [8, 9].

Safe corridor can be transcutaneously recognized in the base of the proximal phalanx through the identification of the central tendon at the MCP joint dorsally. It is safe corridor for the insertion of the K-wire on whichever side of the tendon, which has a wide triangular safe cone dorsolaterally and dorsomedially [4]. In our case, after the identification of the extensor tendon, which was located at the middle dorsal part of the MCP joint, the wires were inserted. By flexing the joint, the fracture was reduced. Then, an antegrade pin was placed through the metacarpal head, crossing the MCP joint and the fracture. Fracture immobilization was held for 3 weeks. Next, the pin was removed. Within the first week, the PIP joint motion was initiated. In a previous study, satisfactory results were achieved in 90% of fractures, which were treated within 5 days after injury [1].

Figure 8. (a) Safe corridors are distinct in each phalanx in flexed position (yellow). (b) Safe corridors are distinct in the interphalangeal joint in extended position (yellow) [4].

Stiffness is one of the most common issues in phalangeal fractures. Finger immobilization for 3 weeks leads to undesirable clinical results [2]. Therefore, in our case, we pulled out the wires after 3 weeks to prevent joint stiffness or other undesirable results. Passive flexion and extension of the MCP joint were achieved after the entry of the K-wire. Further active and passive MCP joint flexion and extension were continued through physiotherapy after the wire was pulled out.

This systematic review presented conflicting results about CRIF with transarticular or extra-articular K-wire entry [3, 10]. We used the extra-articular percutaneous cross-pinning technique for fixation, attributing to our goal of preserving the ROM of the MCP joint and preventing extensive soft tissue damage, which can result in fibrosis and adhesion adjacent to the extensor mechanism. Joshi [2] have retrospective series of 62 proximal phalanx fractures in 53 patients. The patients were treated with closed reduction and extra-articular percutaneous pinning technique. They had an overall satisfaction rate of 90%. Green and Anderson [2] have retrospectively evaluated 26 fractures in 21 patients and conducted closed reduction and extra-articular percutaneous pinning. An early motion program was initiated, and 18 of 21 patients achieved full ROM. Overall, there are no obvious differences in functional outcomes between percutaneous K-wire fixation and open reduction internal fixation of proximal phalangeal fractures [11].

CONCLUSION

Treatment of fractures at the base of the proximal phalanx using K-wires with the extra-articular percutaneous cross-pinning technique can have desirable clinical outcomes, which include restoration of full ROM. The safe portals for the insertion of the K-wire in treating proximal phalanx fractures with the cross-pinning technique must be identified to prevent soft tissue damage, which could result in unfavorable outcomes, including adhesion and joint stiffness.

CONFLICT OF INTEREST

The authors declare that there is no conflict of interests regarding the publication of this paper.

Chapter 340

THE ROLE OF ACUPUNCTURE IN A BREAST CANCER PATIENT WITH CANCER-INDUCED BONE PAIN

***Kemas Abdurrohim, MD, Irma Nareswari, MD
and Diana Oei*, MD***

Department of Medical Acupuncture, RSUPN Dr. Cipto Mangunkusumo,
Universitas Indonesia, Jakarta, Indonesia

ABSTRACT

Bone pain is the most common type of cancer-related pain; it often occurs in cases of advanced cancer that have metastasized to bone, particularly prostate cancer, breast cancer, lung cancer, and multiple myeloma. This type of pain is usually severe, persistent, and hard to manage. Current pain-relieving strategies include the use of strong opioids, bisphosphonates, and radiotherapy. However, these approaches may cause unwanted side effects that affect a patient's quality of life. Acupuncture is an adjuvant therapy for pain relief; it has minimal side effects and may improve a patient's quality of life. This paper discusses a 42-year-old female with cancer-induced bone pain who underwent 10 acupuncture treatments at the LI4 Hegu, SP6 Sanyinjiao, SP9 Yinlingquan, ST36 Zusanli, GB34 Yanglingquan, LR3 Taichong, BL23 Shenshu, and GB30 Huantiao acupoints and experienced improvement in pain.

Keywords: acupuncture, bone pain, cancer, non-pharmacological treatment

INTRODUCTION

Cancer pain is common in cancer patients. However, management of this type of pain is often not optimal. About 40–85% of cancer patients suffer from pain. Cancer pain can be seen in all stages of cancer: 25% of newly diagnosed patients, 33% of patients undergoing treatment, and about 75% of patients with advanced cancer [1].

* Corresponding Author's Email: diana.oei@hotmail.com.

Cancer-induced bone pain (CIBP) is often found in patients with prostate cancer, breast cancer, lung cancer, and multiple myeloma [2-4]. Approximately 50% of patients with bone metastases suffer from bone pain. CIBP is often felt in the lower back, pelvic area, long bones, and ribs [5]. The pain generally worsens as the disease progresses and can be divided into ongoing pain and breakthrough pain [2]. Several studies have suggested that CIBP is a unique and complex type of pain since it is caused by the hyperexcitation of cells in the dorsal horn and involves both neuropathic and inflammatory pathways [6-10].

Figure 1. Modified World Health Organization Analgesic Ladder.

The modified World Health Organization analgesic ladder (Figure 1) [13] describes the mainstream therapies for CIBP [11-14]. However, these approaches are often accompanied by adverse effects, including constipation, nausea and vomiting, drowsiness, urinary retention, itch, myoclonus, loss of consciousness, respiratory depression, opioid-induced hyperalgesia, and pain flare, which can decrease the quality of life in such patients [11, 12, 15]. In addition to conventional therapies, acupuncture has been used to manage cancer pain and improve quality of life in cancer patients with minimal side effects [16].

In this report, we present a case of CIBP treated with manual acupuncture as an adjunct treatment to conventional therapies in a patient with breast cancer.

CASE ILLUSTRATION

A 42-year-old female complained of persistent pain (5 months duration) that radiated from the right hip toward the lateral malleolus. The pain was evident upon sitting or lying

down and relieved when walking. At a follow-up 2 months later, she reported worsening of the pain when walking and sleeping. There were no complaints regarding micturition or passing stool.

The patient had a history of breast cancer that had metastasized to the bone 2 years prior. She had undergone six sessions of chemotherapy and was given an aromatase inhibitor (Aromasin) to limit metastases.

The patient went to Cipto Mangunkusumo Hospital for pain management and was suggested to undergo a bone scan. The resulting bone scan showed an increase in bone metastases, which was deemed responsible for the pain. The metastases were seen in the seventh posterior rib (left), seventh thoracic vertebra, second lumbar vertebra, sacrum, right ilium, right ischium, right acetabulum, and right proximal femur.

Pain was measured using the numeric analog scale (NAS). The patient reported a NAS score of 7, even after treatment with pain medication and radiotherapy.

On physical examination, multiple small masses were seen in her right breast; there were scar tissues under her umbilicus and in the inguinal region as the result of ovariectomy, which was part of her cancer treatment. A positive straight leg raise test and Patrick's test were found in this patient indicating the possibility of nerve root involvement in this patient. There was also pain due to pressure around the GB30 Huantiao acupoint.

Manual acupuncture was then administered to this patient twice per week for 5 weeks using a Huanqiu acupuncture needle (0.25×25 mm and 0.25×60 mm). The chosen acupoints were bilateral LI4 Hegu, SP6 Sanyinjiao, SP9 Yinlingquan, ST36 Zusanli, GB34 Yanglingquan, LR3 Taichong, BL23 Shenshu, and right GB30 Huantiao. Manipulation of the needle was performed until a needling sensation (*deqi*) was achieved; the needle was then left in place for 30 min. Thermal stimulation was also applied to the hip using a TDP lamp.

After the first acupuncture treatment, the patients's pain was reduced to a NAS score of 3. She continued taking pain medication between acupuncture treatments. After the third session, the pain NAS score was 0, and the pain was only felt occasionally at night. However, by the fifth session, the pain had returned at a NAS score of 3 but had migrated to her left hip. After the 10th treatment, the NAS score again returned to 0.

DISCUSSION

The pain suffered by this patient is consistent with the results of the bone scan, which revealed metastases in the hip and lower back regions. Although the physiological mechanisms of bone pain are not fully known, several factors may play a role in the mechanism of CIBP, including the release of proinflammatory mediators causing peripheral sensitization, damage to the periosteum from an increase in osteoclastic activity, microfractures, increased pressure within the bone, periosteal stretching, muscle spasms, nerve root infiltration, and nerve compression due to vertebral collapse. CIBP is likely due to a combination of peripheral and central mechanisms involving both neuropathic and inflammatory pathways [12, 16].

In bone metastases, an increase in levels of receptor activator of nuclear factor kappa-B ligand upsets the balance between bone resorption and formation, causing an increase in osteoclastic activity and destruction of the bone. Such bone destruction may lead to pain via

the stimulation of mechanoreceptors in the periosteum; excessive osteoclastic activity may also damage sensory nerve fibers, causing neuropathic-type of pain. Sensory neurons in the periosteum may also be affected by an increase in mechanical stress within the bone that causes pain and increased sensitization [2, 11].

Tumors are known to contain many inflammatory cells. Local inflammatory cells and tumor cells produce various chemical mediators [prostaglandin, endothelin, tumor necrosis factor (TNF)], interleukin-1 (IL-1)] that can stimulate sensory nerve fibers in bones and cause localized acidosis, in turn sensitizing acid-sensing ion channels such as the transient receptor potential vanilloid receptor 1 (TRPV1). Previous studies have shown the importance of TRPV1 in modulating CIBP [2, 11, 12, 15].

CIBP is a unique type of pain in which increases in dynorphin regulation and c-fos expression are seen in the deep dorsal horn. In rat models of CIBP, repeated activation of primary C-fiber afferents by noxious stimulants resulted in a “wind-up” phenomenon, which is characterized by an escalation of nociception by cells in the dorsal horn. This phenomenon causes central sensitization via the stimulation of wide-dynamic range (WDR) cells, which results in the amplification and prolongation of nociception in the central nervous system. This sensitization causes allodynia and hyperalgesia. CIBP also causes central sensitization via the activation of N-methyl-D-aspartate (NMDA)-type glutamate receptors, which is a feature of chronic pain [12].

Changes in the phenotype of dorsal horn neurons, characterized by an increase in WDR neurons, were also seen in CIBP. These changes result in hypersensitivity to mechanical input and movement-related CIBP [16].

Hu et al., (2012) reported that expression of monocyte chemoattractant protein-1 (MCP-1) and CCR2 increases in the spinal cord as the result of neuronal damage in CIBP. MCP-1 is expressed in primary afferent neurons in the spinal cord and is co-expressed with other noxious neuropeptides, such as substance P, calcitonin gene-related peptide, and TRPV1, causing the release of various proinflammatory cytokines and chemokines that can induce central sensitization and worsen CIBP [17, 18].

In traditional Chinese medicine (TCM), the etiology and mechanism of cancer pain can be categorized into stagnation and cachexia, which are characterized by excess and deficiency, respectively. As a general rule, CIBP in the early and middle stages of cancer is considered excess pain, whereas CIBP in advanced cancer is considered deficient or mixed pain. According to TCM, the key to pain relief is to “unblock” the meridian/channel and regulate the qi/blood [19].

The acupuncture points chosen for this patient were gathered from several case reports and studies of CIBP management [6, 20-23]. Local and segmental points, such as GB30 Huantiao, BL23 Shenshu, ST36 Zusanli, and GB34 Yanglingquan, were used to modulate nociception. The activation of type A and type C nerve fibers during acupuncture manipulation stimulates inhibitory mediators and negative feedback mechanisms related to certain autoreceptors, causing the attenuation of afferent signal transmission distal from the acupuncture points [24]. Segmental points also stimulate A δ fibers in the muscle and skin that synapse with interneurons in the substantia gelatinosa, causing the release of inhibitory neuromodulators, such as enkephalin. This process can decrease the activity of WDR and nociceptive-specific cells, inducing analgesia along the dermatome and its proximal spinal segments [12].

A previous study showed that needling at acupoint GB30 Huantiao decreases the expression of IL-1 β [25]. IL-1 β is known to facilitate nociception in neuropathic and inflammatory pain via several distinct signal transduction pathways. For example, IL-1 β can activate the p38 mitogen-activated protein kinase (MAPK) pathway to cause hyperalgesia; it can also induce the phosphorylation of NR1, a subunit of the NMDA receptor, [25] which plays a role in the transmission of pain in the spinal cord. As previously mentioned, the activation of the NMDA receptor is a feature of chronic pain. Thus, attenuating NMDA receptor activity using acupuncture can help relieve CIBP. A study by Zhang et al., (2008) showed that electroacupuncture at acupoint GB30 Huantiao attenuates the upregulation of preprodynorphin mRNA and dynorphin, resulting in a lessening of hyperalgesia [21].

Several studies have also shown that needling at acupoint ST36 Zusanli along with other acupuncture points can lead to a decrease in the levels of proinflammatory mediators, such as TNF- α , MCP-1, and IL-6, and an attenuation of the expression of Toll-like receptor 4 (TLR4), myeloid differentiation factor 88, and NF- κ B, resulting in CIBP relief [26-28]. A study of adjuvant-induced arthritis showed that needling the ST36 Zusanli, BL23 Shenshu, and GB39 Xuanzhong acupoints increased the expression of vasoactive intestinal peptide, which is negatively correlated with TLR4 signaling [29]. Both TLR4-p38 MAPK and MCP-1 (with CCR2 in the dorsal horn) play roles in nociception in CIBP [17, 18]. Therefore, attenuating such proinflammatory mediators may improve CIBP. A study conducted in a mouse inflammatory pain model showed that low-frequency electroacupuncture at acupoint ST36 Zusanli attenuated the expression of TRPV1 and TRPV4, which are crucial receptors involved in nerve excitation [30].

Li et al., (2017) showed that acupuncture at the GB34 Yanglingquan acupoint increased progranulin (PGRN) levels. PGRN is a multi-functional growth factor expressed by various cells that plays a role in wound healing, cancer, and inflammation. An increase in PGRN during acupuncture can attenuate the activation of NF- κ B, which is mediated by the competitive binding of TNF- α to TNFR1 and TNFR2 [31]. Chang et al., (2014) showed that needling both SP9 Yinlingquan and ST36 Zusanli acupoints decreased c-Fos expression in laminae II and V in the dorsal horn of the spinal cord. This decrease in c-Fos improves pain caused by inflammation. Acupoint SP6 Sanyinjiao, which decreases proinflammatory macrophages while increasing anti-inflammatory macrophages and IL-10 levels, was chosen for this patient due to its antinociception and anti-inflammatory effects [32]. The combination of the LI4 Hegu, LR3 Taichong, ST36 Zusanli, and SP9 Yinlingquan acupoints can effectively decrease nociceptive pain due to inflammation [33].

As it is known that a decrease in nociception in the dorsal horn via A δ inputs can be maintained via regular acupuncture sessions [12, 34]. Our patient was advised to undergo acupuncture twice per week for 5 weeks to achieve optimal outcomes.

CONCLUSION

This report describes the benefits of acupuncture as a complementary therapy for CIBP management in a patient who suffers from CIBP despite administration of pain medication and radiotherapy.

ABSTRACT

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL) is an uncommon subtype of intestinal lymphoma that is usually found in Asian populations. MEITL causes non-specific gastrointestinal-related symptoms; thus, it is often overlooked and misdiagnosed, resulting in complications and improper therapeutic approaches. A 75-year-old Asian female was admitted to the emergency room with signs and symptoms of ileal obstruction. She had no history of celiac disease. Surgical resection was performed; the tumor consisted of small- to medium-sized tumor cells arranged in a monomorphic and diffuse pattern. The tumor was positive for CD3 and CD56 but negative for CD8. She was diagnosed with MEITL. Although most MEITL tumors are positive for CD3, CD56, and CD8, CD8-negative MEITL has been reported in some studies and is thought to originate from double-negative intraepithelial lymphocytes. We described a rare case of MEITL with an unusual negative CD8 expression.

Keywords: intestinal lymphoma, monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL)

INTRODUCTION

Monomorphic epitheliotropic intestinal T-cell lymphoma (MEITL) is a rare type of intestinal lymphoma that arises from intraepithelial lymphocytes (IELs). MEITL was

^{*} Corresponding Author's Email: agnharahap@gmail.com.

formerly designated as a subtype of enteropathy-associated T-cell lymphoma (EATL) type II. It was recognized as a different entity in the latest WHO classification because of its apparent morphological and immunophenotypic features [1, 2].

Despite its rarity, MEITL occurs worldwide and is the most common type of primary intestinal T-cell lymphoma in Asian populations. MEITL usually manifests with non-specific signs and symptoms, which makes it difficult to diagnose, leading to a higher risk of misdiagnosis and complications as a result of inaccurate therapeutic approaches and procedures. Symptoms range from abdominal pain, weight loss, and diarrhea to intestinal obstruction, which can lead to perforation and bleeding. MEITL is clinically aggressive and generally diagnosed late, with poor prognosis at the time of diagnosis. Therefore, MEITL should always be considered as a differential diagnosis in intestinal tumors, particularly in tumors present in the small intestine [1, 3–5].

MEITL has distinct morphologic and immunophenotypic features. It is composed of monomorphic small- to medium-sized tumor cells that are positive for CD3, CD56, and CD8. However, these expressions vary in some cases, making diagnosis even more difficult. Variations in marker expressions depend on the diverse cellular origin of the tumor.

We present a case of a 75-year-old female with intestinal obstruction due to MEITL with unusual negative CD8 expression.

CASE

A 75-year-old Asian female admitted to the emergency room presented with fever, weakness, nausea and vomiting, abdominal distention, pain, and diarrhea. She had been experiencing abdominal discomfort for approximately 2 months before admission and was assessed as having gastritis. She also had difficulty eating but had no history of celiac disease. A physical examination did not identify any masses or lymphadenopathy at other sites. The laboratory examination showed leukocytosis (14,300/ μ l) and increased serum Ca125 (185.5 U/mL) levels. Her LDH level was within the normal range (308 U/L). HLA typing was not performed. Chest X-ray showed no mediastinal or lymph node enlargement (Figure 1).

Figure 1. Chest X-ray. No mediastinal or lymph node enlargement was observed.

An abdominal ultrasound showed intestinal inflammation with segmental dilatation and a heterogenous lesion in the lower abdomen compatible with either a fecal mass or tumor. Abdominal computed tomography showed intestinal wall thickening and an ileal mass responsible for obstruction, with dilatation of the proximal segments (Figure 2).

A small intestinal resection was performed. Macroscopically, the tumor measured 4×4×2 cm; it bulged into the serous layer and was whitish and rubbery in consistency. The non-tumorous mucosa showed no marked abnormalities (Figure 3).

Histopathologic examination of the ileal tissue resection showed diffuse transmural proliferation of monotonous medium-sized lymphoid cells with dispersed chromatin, inconspicuous nucleoli, and clear cytoplasm. The tumor lacked inflammatory infiltrates. The adjacent mucosa showed blunting villi and ulcerations. There was also evidence of epitheliotropism characterized by infiltration of lymphocytes in the epithelium. No enteropathy changes (crypt hyperplasia and villous atrophy) or necrosis were found (Figure 4).

Figure 2. Abdominal CT scan showing intestinal wall thickening and an obstructing mass in the ileum, with proximal intestinal and gastric dilatation.

Figure 3. The tumor appeared as a bulging, whitish, and rubbery mass in the ileal wall (formalin fixed tissue).

Figure 4. Histopathological features. (a, b) The affected intestinal mucosa showed blunting of the villi and ulceration, H&E 40 $\times$. (c) There was a diffuse transmurular proliferation of lymphoid cells, H&E 40 $\times$. (d) The tumor cells are arranged in a monotonous and diffuse pattern, H&E 100 $\times$. (e, f) The tumor consists of medium-sized lymphoid cells with dispersed chromatin, inconspicuous nucleoli, and clear cytoplasm, H&E 400 $\times$.

The tumor cells were positive for CD3, CD7, CD56, T-cell intracytoplasmic antigen (TIA)-1, and perforin. The Ki67 proliferation index was 70–80%. Other markers such as CD8, CD4, CD30, CD5, CD20, CD79a, CD10, granzyme B, and Epstein–Barr virus-encoded small RNA (EBER) *in situ* hybridization were all negative. Several important markers (megakaryocyte-associated tyrosine kinase (MATK), CD103, TCR $\alpha\beta$, and TCR $\gamma\delta$) were not available (Figure 5 and 6).

Figure 5. Immunohistochemistry profile. (a) AE 1/3, negative, 100×; (b, c) CD3, diffusely positive, 100× and 400×; (d) CD7, diffusely positive, 400×; (e) Ki67, positive in 70–80% of tumor cells, 400×; (f) Bcl-2, positive, 400×; (g) TIA1, positive, 400×; (h) perforin, positive, 100×; (i) CD56, positive, 400×; (j) CD20, negative, 100×; (k) CD4, negative, 400×; and (l) CD8, negative, 400×.

The immunohistochemistry features are more identical to those of extranodal NK/T-cell lymphoma, nasal type (ENKTL). However, due to the negative EBER test and no manifestation in nasal, the patient was diagnosed with MEITL. The patient gave up treatment and died within 1 month after surgery.

DISCUSSION

The gastrointestinal tract is the most common extranodal site of lymphoma; 30–40% of all extranodal lymphomas occur here. However, primary lymphoma of the gastrointestinal tract is very rare and constitutes only approximately 1–4% of gastrointestinal malignancies. Most cases of gastrointestinal lymphoma belong to the non-Hodgkin lymphoma (NHL) subtype, such as diffuse large B-cell lymphoma, mucosa-associated lymphoid tissue lymphoma, follicular lymphoma, Burkitt lymphoma, mantle cell lymphoma, peripheral T-cell lymphoma (PTCL), ENKTL, adult T-cell leukemia/lymphoma (ATLL), EATL, and MEITL [6–10].

The current patient presented with gastrointestinal-related signs and symptoms due to intestinal obstruction from an ileal tumor, which can be caused by intestinal lymphoma. According to Dawson [11], intestinal lymphoma is considered primary if it has the following clinical characteristics: (1) no palpable superficial lymphadenopathy, (2) no obvious enlargement of mediastinal lymph nodes due to chest radiographs, (3) normal white blood cell counts (total and differential), (4) predominating bowel lesions in laparotomy, with the affected lymph nodes being in its immediate neighborhood, and (5) no lymphoid tumor involvement in the liver or spleen. The physical, laboratory, and radiologic examination of our patient showed neither lymphadenopathy nor tumor in the liver and spleen. Although the leukocyte count was above normal levels, the signs and symptoms fit four of Dawson's five criteria for primary gastrointestinal lymphoma. The high leukocyte count was likely due to infection because the patient also presented with fever.

The histopathologic features showed medium-sized, monomorphic tumor cells with round nuclei that were arranged in a diffuse pattern, suggesting NHL. Although most primary gastrointestinal lymphomas are of B-cell lineage, the immunophenotype of this patient was CD3-positive and CD20-negative, suggesting that the tumors were of T-cell origin, which occurs in only 9% of primary gastrointestinal lymphomas [8, 11].

The differential diagnosis of T-cell lymphoma in the intestine includes MEITL, EATL, ENKTL, PTCL, ATLL, and gamma delta T-cell lymphoma. The clinical, histopathological, and immunohistochemistry findings of this patient displayed tendencies associated with

primary intestinal T-cell lymphoma. However, considering its rarity, we could not yet exclude the possibility of the tumor representing the extranodal involvement of other T-cell lymphomas [1, 3, 4, 12].

In this case, the immunophenotype of the tumor fit that of MEITL and ENKTL the best. The clinical features, morphology, and immunophenotype of MEITL and ENKTL are described in Table 1.

Our patient was an Asian female in her 70s; therefore, she had a supporting demographic background for both MEITL and ENKTL. The tumor was present as a mass in the ileum and thickening of the intestinal wall with no involvement of other areas was noted; this manifestation is more commonly found in MEITL.

MEITL is composed of monomorphic small- to medium-sized tumor cells, with round and regular nuclei, finely dispersed chromatin, inconspicuous nucleoli, and clear cytoplasm. The tumor cells also show prominent epitheliotropism. MEITL has no known association with celiac disease; thus, the non-neoplastic areas are absent of the features found in celiac disease. The villous architecture is distorted with broad villi as a result of tumor cell expansion in the lamina propria, but no inflammatory background is present. The morphologic features in our case fit those of MEITL [1, 3–5].

The MEITL immunophenotype is quite distinctive: CD3, CD8, and CD56 are positive in most cases, with CD8 and CD56 being highly specific markers. MEITL is negative for CD4 and CD30 and is often negative for CD5 since most MEITL cases express gamma delta T-cell receptor (TCR). The most frequently expressed TCR in MEITL is of the gamma subtype, but some cases express TCR beta, TCR gamma and beta, and CD8 alpha homodimers. Some studies have also reported silent TCR tumor cells. TIA1 is usually positive, whereas the expressions of perforin and granzyme are inconsistent. MATK is expressed in more than 80% of tumor cells in most cases and is a helpful marker to differentiate MEITL from EATL [1, 16, 17].

The tumor cells in our case were positive for CD7, CD56, TIA1, and perforin and negative for CD5, CD4, CD30, and granzyme B, which is in line with the MEITL immunophenotype according to the literature. Intriguingly, CD8 was not expressed. There are, however, some previous reports of CD8-negative MEITL [16, 18–20].

MEITL arises from several subtypes of intestinal IELs that express different types of surface receptors, which is resembled in the immunophenotype. Most IELs express TCR; however, some studies have recently reported TCR-negative IELs. In addition to TCR expression, there are also variations in CD4 and CD8 expressions. During the differentiation process, most lymphocytes undergo positive selection in the thymus before differentiating into single-positive T-cells and migrating into the intestine. By contrast, the remaining lymphocytes are double negative when transferred into the intestine. The latter then differentiate into single-positive T-cells following antigenic stimulation. Both the TCR-positive and TCR-negative and single-positive and double-negative T-cells have the potential to transform into MEITL and affect its immunophenotype. MEITL originating from the double-negative T-cells presents with CD3⁺ CD8[–] tumor cells, as in our case. Perforin was positive in this case, which is an uncommon feature in double-negative T-cells and is thus considered aberrant. However, perforin transcription process starts in the stage of double-negative, making it possible to be detected in unusual cases [16, 18, 19].

Table 1. Clinical, morphologic, and immunophenotypic features of MEITL and ENKTL [1,4,13–15]

	MEITL	ENKTL
Clinical features	Abdominal pain, obstruction or perforation, weight loss, diarrhea, gastrointestinal bleeding.	Nasal obstruction-related signs and symptoms in most cases. Intestinal lesions manifest as perforation or gastrointestinal bleeding.
Median age	60 years old	44-54 years old
Male:female ratio	2:1	2:1
Epidemiology	Asia, Hispanic	Asia, Mexico, Central and South America
Frequency	1% of NHL	10% of NHL
Localization	Small intestine, jejunum more often involved than the ileum. It can disseminate to extranodal sites (stomach, large bowel) and regional lymph nodes.	Most commonly involves the nasal cavity. Other sites of involvement include upper aerodigestive tract, skin, soft tissue, gastrointestinal tract, and testes.
Primary/secondary intestinal lesion	Primary	Secondary involvement is more common than primary
Gross appearance	Plaques and nodules	Mass and perforation
Cytological features	Small to medium-sized tumor cells, monomorphic	Broad cytological spectrum. Most tumors consist of medium-sized cells or a mixture of small and large cells.
Necrosis	Uncommon	Common
Inflammatory background	Uncommon	Heavy, can mimic inflammatory process
Mucosa away from tumor	Normal	Normal
CD3	+	+
CD5	–	–
CD56	+	+
CD4	–	–
CD8	+	–
CD7	+	+
CD30	–	±
TIA1	+	+
Granzyme B, perforin	variable	+
HLA-DR	–	+
MATK	+	+
EBV infection	No known association	Very strong association

ENKTL was considered as a differential diagnosis in this case because of the more identical immunophenotype and higher prevalence compared with MEITL. However, when found in the gastrointestinal tract, ENKTL most commonly manifests as an extranodal spread rather than as a primary lesion. According to Dawson's criteria [11], the tumor in our case

was more likely a primary intestinal lymphoma. ENKTL consists of small, medium, large, or anaplastic tumor cells and is usually accompanied by coagulative necrosis admixed apoptotic bodies and inflammatory infiltrate. These morphologic features are not in line with those of our case since there was no inflammatory infiltrate or necrosis. The immunophenotype of ENKTL is CD3+, CD56+, and CD8–, which is identical with the patient's immunophenotype. However, ENKTL is strongly associated with Epstein–Barr virus infection. Although the immunohistochemistry profile might be compatible, the clinical and morphologic features and the negative EBER ruled out ENKTL.

Another possible differential diagnosis of this patient was EATL. EATL is commonly found in Northern Europe, usually occurs in the small intestine, and is associated with celiac disease. The tumor cells are polymorphic and are composed of pleomorphic medium to large cells with prominent nucleoli. EATL is accompanied by an inflammatory background and often necrosis. The features of celiac disease can be found in the adjacent mucosa, particularly in the jejunum. The tumor cells are usually CD3+, CD5–, CD7+, CD4–, CD8–, and CD103+. They also express cytotoxic granule-associated proteins, e.g., TIA1, granzyme B, and perforin. CD30 expression differs according to the cytomorphology, but almost all large-cell EATL are CD30+. In this case, EATL was unlikely because of the demographic background of the patient, no history of celiac disease, and the irrelevant morphologic features. CD103 and MATK immunostaining was necessary to confirm the diagnosis, but these procedures were not available in our country [1, 21].

The patient underwent surgical resection and then stopped treatment and died 1 month later. There is currently no established treatment for MEITL. In most cases, patients undergo surgical resection due to the emergency presentation or the need for a histopathological examination. In our case, the surgery was performed because of the ileal obstruction and to prevent perforation. Surgery followed by chemotherapy tends to have a better outcome than surgery alone. However, the most efficient chemotherapy regimen has yet to be discovered. The most commonly used chemotherapy regimens are CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone), SMILE (dexamethasone, methotrexate, ifosfamide, L-asparaginase, and etoposide), and IVENTX (ifosfamide, vincristine, and etoposide/methotrexate). MEITL is considered aggressive and has a poor prognosis, even when treated using chemotherapy, with a median overall survival of 7 months. Nonetheless, some studies showed that early detection and treatment result in better therapy response and even long-term survival. Some studies also reported the use of hematopoietic stem cells [16, 18, 20].

CONCLUSION

Primary intestinal lymphoma is very rare and often misdiagnosed. Various subtypes of lymphomas can occur in the gastrointestinal tract, with diverse morphology and immunophenotypes. We reported a rare case of primary lymphoma of the gastrointestinal tract, with the immunophenotype suggesting ENKTL. However, because of its clinical and morphologic features and negative EBER test, the patient was diagnosed with CD8-negative MEITL. CD8 and CD56 are the highly specific markers for MEITL, but they might not be expressed in particular cases. The expression of T-cell markers depends on the cellular origin of the tumor. MEITL arises from IELs residing in the intestine, which have diverse

phenotypes and are present in various stages of differentiation. Therefore, it is possible for MEITL to have uncommon and aberrant marker expressions that should not be overlooked.

Universitas Indonesia, Jakarta, Indonesia

ABSTRACT

Clear cell papillary renal cell carcinoma is an indolent neoplasm composed of clear epithelial cells arranged in tubules and a papillary structure, with predominantly linear nuclear alignment away from the basement membrane. In this paper, we report our experience of diagnosing a rare case of clear cell papillary renal cell carcinoma. The patient was a 50-year-old male with a chief complaint of abdominal pain. A computed tomographic abdominal scan revealed a large heterogeneous multicystic mass on the left kidney. On the basis of the macroscopic examination, microscopy, and immunohistochemical staining, we diagnosed the tumor as a clear cell papillary renal cell carcinoma. This tumor is an uncommon variant of a renal cell neoplasm that has distinct histological and immunohistochemical characteristics. Pathologists should be aware of this entity because the biological behavior of this tumor is very different from that of conventional clear cell carcinoma.

Keywords: clear cell papillary renal cell carcinoma, renal cell carcinoma

INTRODUCTION

Renal cell carcinoma (RCC) is the most common malignancy of the kidney, accounting for up to 90% of renal neoplasms in adults. The most common type is clear cell RCC,

* Corresponding Author's Email: budiana.t@gmail.com.

followed by papillary RCC. Clear cell RCC is a malignant tumor composed of cells with clear or eosinophilic cytoplasm. Papillary RCC has a papillary or tubulopapillary structure and is often circumscribed. The papillae are separated by delicate fibrovascular cores with foamy macrophages and hemosiderin. Other subtypes are Xp11.2 translocation-associated RCC and clear cell papillary RCC (CCPRCC) with papillary architectures and a clear cell morphology [1, 2].

CCPRCC is an indolent renal tumor composed of a single layer of cells with clear cytoplasm with tubules and a papillae structure. Tickoo et al. reported a lesion appearing in patients with end-stage kidney disease, but these tumors could be found in otherwise normal kidney. Aydin et al. in a large series reported similar tumors as clear cell tubulopapillary RCC (CCTPRCC) [1, 3-5].

Patients with CCPRCC usually are asymptomatic and sometimes present with abdominal pain. Some tumors are found in the follow-up after dialysis. This tumor accounts for 1%-4% of all resected renal neoplasms. The ages of patients range from 18 to 88 years, with a mean of 70 years. There is no sex predilection [1, 6]. The tumor sizes range from 0.2 to 7.5 cm (mean, 2.0; median, 1.8 cm). The tumor is commonly well defined and well encapsulated with cystic changes, and it sometimes presents as a solitary mass. CCPRCC is characterized by tubular papillary infoldings, and acinar cystic, ribbon-like, and solid patterns are seen in varying proportions. The tumor cells are cuboidal to low columnar, with clear cytoplasm or scant eosinophilic cytoplasm and uniform nuclei with inconspicuous nucleoli arranged linearly away from the basement membrane. Immunohistochemically, these tumors show positivity for cytokeratin 7 (CK7), carbonic anhydrase IX (CA9), and vimentin and negativity for CD10, RCC marker, and alpha-methylacyl-CoA racemase (AMACR). CCPRCC is different from conventional cell RCCs that are CK7 negative and CD10 positive and from papillary cell carcinomas that are CK7, CD10, and racemase positive [6-9].

Because of its rarity, we report a case of CCPRCC that had overlapping features with those of papillary RCC and clear cell RCC but different genetic and immunohistochemical features and seemed to be indolent, with no detectable metastases.

CASE REPORT

A 50-year-old male patient came to the Islamic Jakarta Hospital on December 20, 2014, with a chief complaint of flank pain and hematuria. He had experienced intermittent flank pain since 1 year prior to hospital admission. During that time, he had gone to a doctor and been told that he had muscle pain. He had a 4-year history of hypertension and was regularly taking captopril 2 × 25 mg. The patient also had experienced hematuria but had ignored it. A history of pain during urination was denied. He had experienced weight loss and felt a mass in his left abdomen 6 months prior to hospital admission. He had a smoking habit of 3-4 cigarettes per day.

On December 20, 2014, he felt severe flank pain and hematuria. He then felt nausea and experienced vomiting. In the Islamic Jakarta hospital, he underwent a computed tomography (CT) abdominal scan without contrast, which revealed a large heterogeneous 9.5 × 11 × 14-cm mass on the left kidney that had already passed through the capsule but not the Gerota fascia. A focus of calcification was also observed.

Figure 1. A Coronal section of the abdomen CT Scan shows a large ($9.5 \times 11 \times 14$ cm) heterogeneous mass that has already passed through the capsule but has not yet invaded the Gerotafascia. Calcification is also shown. B. Axial section of the abdomen CT Scan.

Table 1. Patient's laboratory results

Type of examination	Result	Unit
Hemoglobin	13.9	g/dL
Hematocrit	41.6	%
Erythrocyte	4.72	$10^6/\mu\text{L}$
Leukocytes	7390	μL
Platelets	210.000	μL
Urea	35	mg/dL
Creatinine	1.6	mg/dL
Glomerular filtration rate	50,9	$\text{mL}/\text{min}/1.73\text{m}^2$
Sodium	143	mEq/L
Potassium	4.94	mEq/L
Chloride	100	mEq/L

The urologist suggested that the patient needed surgery in Dr. Cipto Mangunkusumo Hospital. On February 3, 2015, a nephrectomy was performed. The results of the laboratory testing performed on February 2, 2015, are presented in Table 1.

The specimen was sent to the anatomical pathology laboratory. On macroscopic examination, the size of the left kidney was $18 \times 11.5 \times 8.5$ cm, and the outer surface was smooth, brown in color, and rubbery in consistency. A cut surface showed a multicystic partially solid mass that filled almost all of the kidney parenchyma. The size of the tumor was $17 \times 6 \times 5$ cm. The mass had infiltrated the pelvicalyceal system but had not penetrated the capsule. A microscopic examination showed that the epithelial tumor had an acinar, multicystic, solid papillary structure. The tumor cells had small, hyperchromatic, vesicular nuclei located on the apical side of the cell. The cytoplasm was mostly clear. The stroma was fibrotic and had been infiltrated by inflammatory cells. The tumor had infiltrated the capsule but had not yet penetrated the perirenal fat. The tumor was diagnosed as a clear cell papillary RCC.

On April 19, 2016, we performed immunohistochemistry staining, including CK7, CD10, AMACR, vimentin, high molecular weight cytokeratin (HMWCK), CK8, CK18, epithelial membrane antigen (EMA), and Ki67 of the tumor to provide supporting results for the diagnosis. The results showed that the tumor was positive for CK8, CK18, EMA, CK7, CD10, HMWCK, and vimentin and negative for AMACR and Ki67 < 1%.

DISCUSSION

CCPRCC is a low-grade RCC that occurs in both end-stage kidney disease and normal kidneys and is usually located in the renal cortex. More than 95% of tumors are pT1 at presentation and are rarely multilocal or bilateral [6, 7]. Radiographically, CCPRCC is located mid-pole in the kidneys. Some studies have reported that CCPRCC showed frequent heterogeneity suggestive of a mixed solid-cystic nature, and homogeneous solid appearing tumors have also been seen [1, 2, 6].

Figure 4. A. Positive staining for CK8 (400×). B. CK18 (400×). C. EMA (400×). D. HMWCK (400×). E. CK7 (400×). F. CD10 (400×).

These tumors are often small, well circumscribed, and well encapsulated. Surface coloration is variable and necrosis is absent. Histopathologically, CCPRCC commonly shows

cystic, tubular, acini, papillary, ribbon-like, and solid patterns in varying proportions. The cells are cuboidal to low columnar, with clear or scant eosinophilic cytoplasm, round uniform nuclei and a low Fuhrman nuclear grade (1 or 2). The cells are arranged linearly away from the basement membrane or toward the apical surface. It is believed that CCPRCC has a better prognosis than those of clear cell RCC and papillary RCC. Smooth muscle and fibrous stroma in varying amounts have been noted. There is no tumor necrosis, perirenal invasion, or lymphovascular invasion in CCPRCC [2, 3, 6].

Figure 5. A. Vimentin (+) (400×). B. Negative for AMACR (400×). C and D. Ki67 < 1% (100× and 400×).

Immunohistochemically, tumor cells usually show positive expression for cytokeratin 7, CA9, hypoxia-inducible factor-1, glucose transporter 1, HMWCK, paired box 2 (PAX2), PAX-8, and smooth muscle actin but negative for AMACR, RCC Ma, TFEB, TFE3, parvalbumin, vinculin, and cathepsin K. Most tumors are negative or focally positive for CD10 [1, 9-13]. In renal cell tumors, CK7 is often used to distinguish ccRCC and its differential diagnosis. PRCC and chromophobe RCC are positive for CK7. CCPRCC is diffusely positive in a membranous pattern, which is useful in distinguishing between conventional clear cell carcinoma CCPRCC. CA9 is a hypoxia-induced protein and predominantly positive in clear cell RCC. CA9 is expressed in cup-shaped distribution in CCPRCC. CA9 is useful in differentiating papillary RCC with clear cell changes from clear cell RCC and CCPRCC. CCRCC and CCPRCC are positive for CA9, whereas PRCC is completely negative or may be focally positive. AMACR is usually negative in CCPRCC and shows diffusely strong cytoplasmic staining in PRCC. CD10, a proximal tubule marker, is

positive in conventional clear cell RCC with a membranous pattern [6, 9, 11, 14]. CD10 is variably expressed in most tumors and shows focal staining [15].

This tumor generally lacks genetic abnormalities observed in either conventional clear cell RCC or papillary RCC. CCPRCC does not harbor the chromosome 3p deletions that occur in clear cell RCC or demonstrate trisomies 7 and 17 or loss of Y in papillary RCC. Both mutations and methylation of the VHL gene promoters have not been reported to date [16-18].

Figure 6. CCPRCC. A. Macroscopic view of the tumor showing a tan cut surface with a mixed cystic/solid appearance. B. Shown is a pink-tan cut surface with solid architecture and a thin capsule [8].

Figure 7. (a) CCPRCC with papillary architecture (40 $\times$); (b) Nuclei situated away from the basement membrane (400 $\times$) [9].

The key to distinguishing between CCPRCC and CCRCC includes the pink-tan cut surface and nuclear positioning away from the basement membrane in CCPRCC and golden-yellow cut surface, mitoses, necrosis, vascular invasion, and network of small thin-walled blood vessels in CCRCC. Often, CCRCC is positive for CD10, PAX8, and CA9 and negative for CK7, with variable results for AMACR. Deletion of chromosome 3p and mutation of the VHL gene are seen in CCRCC [1, 15-19]. Macroscopically, papillary RCC is usually well circumscribed and surrounded by a fibrous pseudocapsule. Immunohistochemically, PRCC often shows positivity for CK7, HMWCK, AMACR, RCC marker, and CD10. CK7 expression is more common in type 1 PRCC than in the type 2 tumor [6, 9]. Multilocular

cystic renal cell neoplasms of low malignant potential are indicated by septated, variably sized, thin-walled cysts separated from the uninvolved renal tissue by a fibrous capsule.

Figure 8. Immunohistochemical staining results. (a) PAX-8, 400x; (b) CA9, 400x; (c) AMACR, 400x; (d) CK7, 400x [9].

These clear cells show low-grade nuclear features lining the cystic spaces within a fibrous septa, although solid areas are, by definition, absent. CCPRCC is strongly positive for cytokeratin 34 and betaE12 and negative for AMACR [1, 8, 9]. Multilocular cystic renal cell neoplasms of low malignant potential also show mutations of the VHL gene and deletion of chromosome 3p. Another differential diagnostic is an RCC with Xp11.2 translocations. The most distinctive and common pattern is the presence of a papillary architecture composed of clear cells with high-grade nuclei and some stromal hyaline nodules and psammomatous calcifications. The Xp11.2 translocation type shows the TFE3 protein in nuclear staining [8, 20].

CONCLUSION

In summary, CCPRCC is a relatively common renal cell neoplasm. Pathologists should be aware of the common incidence of this entity and its overlapping features with other RCCs to avoid the misclassification of CCPRCC as a CCRCC and vice versa. In equivocal cases, immunohistochemical stains such as CK7, AMACR, or CD10 are helpful in determining the correct diagnosis.

RARE CASE OF MYELOLIPOMATOUS METAPLASIA WITHIN AN ADRENOCORTICAL ADENOMA

ABSTRACT

The actual incidence of adrenocortical adenoma (ACA) remains unknown. Data obtained from 2011 to 2015 in Cipto Mangunkusumo Hospital have revealed that only 14 patients presented with adrenal neoplasms; of these patients, 11 were diagnosed with ACA. Myelolipomatous metaplasia is characterized by the presence of foci of hematopoietic cells comprising erythroids, myeloids, and megakaryocytes within a tumor. This metaplasia is an extremely rare finding in adrenal tumors, particularly in ACA. The pathogenesis of myelolipomatous metaplasia remains unclear. Herein, we report the case of a 40-year-old man who presented with a mass in his abdomen. Without any contributory signs and symptoms, the size of the mass increased within 4 months of diagnosis. Computed tomography of the abdomen showed a heterogenous mass in the right suprarenal region with fine demarcated outlines, and the result was indicative of an adrenal carcinoma. The patient underwent adrenalectomy. Based on hematoxylin & eosin (H&E) staining and immunohistochemical analysis, the mass was confirmed to be a non-functional ACA with a myelolipomatous metaplasia. The case was uneventful, and the patient was then discharged with recommendation of an annual follow-up. ACA is a rare type of tumor. Myelolipomatous metaplasia found within an adenoma of the adrenocortex is an even more uncommon finding. The correlation between clinical, radiological, and pathological examination results must be assessed for a more accurate diagnosis. The combination of H&E staining and immunostaining is helpful in facilitating the diagnosis of adrenocortical tumors and metaplasia within the tumor.

Keywords: adenoma; adrenal; myelolipomatous metaplasia

INTRODUCTION

The adrenal gland is a 4-g organ that lies in the suprarenal region. It can be divided into two regions (cortex and medulla). Each zone secretes different hormones and has its own functions. Adrenal neoplasm is defined as a neoplasm arising from the adrenal cells. A tumor arising from the cortical area of the adrenal gland is basically classified as follows: benign adrenocortical adenoma (ACA) and malignant adrenocortical carcinoma (ACC) if invasion is observed [1].

Nodules that are suspected as neoplasms are commonly identified in autopsies. Some are discovered incidentally during annual check-up or imaging screening for other causes. These nodules are referred to as adrenal incidentaloma. Approximately 80% of adrenal incidentaloma is benign and does not secrete hormones (non-functional). Symptoms may be observed depending on tumor location and whether they are functional or not [1, 2].

The actual incidence of ACA is unknown. Data obtained from 2011 to 2015 in Cipto Mangunkusumo Hospital have reported that only 14 patients presented with adrenal neoplasm; of these patients, 11 were diagnosed with ACA, which is typically a unilateral, solitary, and benign neoplasm. With the widespread use of computed tomography (CT) scan of the abdomen, the diagnosis of such condition is increasing. Some studies have reported that the incidence of non-functional adrenal tumors varies between 1.4% and 8.7% based on autopsy studies. The prevalence of adrenal incidentaloma increases with age, and no differences were observed in terms of prevalence based on race and sex [2, 3].

Different types of metaplasia can develop within the adrenal gland. Occasionally, lipomatous foci or bone cell metaplasia can be found. Myelolipomatous metaplasia within an ACA is an extremely rare cause of adrenal incidentaloma. In 2008, only 17 cases of such condition were reported in the English and Japanese literature. The present study aimed to present a rare case of myelolipomatous metaplasia within an ACA and to establish an effective diagnostic approach from the view point of a pathologist if such condition will be encountered in the future [4].

CASE REPORT

A 40-year-old Indonesian male patient was referred by his office physician to the internal medicine department of a hospital in Jakarta in October 2014. The patient was required to undergo an annual check-up resulting in the incidental finding of a large mass in his abdomen. The patient's family and past medical history was not significant. He was free of symptoms, such as palpitation, weight loss, and hypertension. His electrocardiograph and chest radiograph results showed no abnormalities. The general internist performed

ultrasonographic examination and found a mass in the abdomen (Figure 1). A hyperechoic lesion was observed in the right lobus of his liver. The patient was suspected to have a hepatic cellular carcinoma, and the differential diagnosis were hemangioma or a focal fatty infiltration. The internist then recommended whole abdominal contrast-enhanced CT scan and laboratory work up.

The patient had a follow-up consultation a week later with the CT scan and laboratory test results. He was non-reactive for hepatitis C and had normal blood glucose level (fasting glucose level of 85 mg/dL and 2-hour post prandial level of 109 mg/dL), and the following tumor markers were assessed: alpha-fetoprotein (AFP), Ca 19.9, and carcinoembryonic antigen (CEA). The CEA and AFP levels of the patient were within normal limits (CEA: 2.71 [normal value: ≤ 3 ng/mL] and AFP: 2.13 [range: 0–40] ng/mL). The Ca 19.9 level was elevated, which was twice than the normal limit (83.79 U/mL [normal value: < 37 U/mL]). The CT scan result showed a heterogenous mass in the right suprarenal region with fine demarcated outlines, and such result indicated an adrenal carcinoma. The differential diagnosis were changed to adrenal adenoma or adrenal hemorrhage (Figure 2). The patient was then referred to an endocrinologist.

The patient sought consultation from an endocrinologist 4 months after, and the size of the mass increased based on ultrasonographic examination (Figure 1). In February 2015, his body mass index was above the normal limit (26 kg/m^2). His blood pressure was slightly elevated (138/91 mmHg). However, the patient's heart rate, respiratory rate, and temperature were normal (99 beats/minute, 17 cycles/minute, and 36.5°C , respectively). The endocrinologist requested for routine blood test, liver function test, uric acid, glucose, bleeding time and electrolyte. All of his laboratory test came back with normal results.

Based on this finding, the endocrinologist referred the patient to a urologist. Three days after, the urologist performed adrenalectomy. The right adrenal gland was resected and was sent to the Department of Anatomical Pathology at the same hospital. The specimen measured $11.0 \times 10.0 \times 7.0 \text{ cm}^3$, and was a round capsulated mass with fine demarcated outlines, most of which appeared yellow with hemorrhagic areas on the cut surface. Small brown-black lesions that vary in size ($0.4\text{--}3.0 \times 2.0 \times 2.0 \text{ cm}^3$) were observed (Figure 3).

Histologically, the suprarenal tumor showed a mass that was demarcated with a well-developed fibrous capsule. On the peripheral side, there were ACA and brown-black lesions with fat tissues and widely hemorrhagic areas, hematopoietic cells, fibrotic areas, and brownish pigmentations. No signs of malignancies were observed (Figure 4). Immunohistochemistry staining was conducted at the Ciptomangunkusumo Hospital, and results showed positivity for inhibin, Wilms tumor 1 (WT1), neuron-specific enolase (NSE), vimentin, synaptophysin, Melan-A, calretinin, AE 1/3, and chromogranin as well as low positivity for Ki-67 in the area with suspected ACA. The brown-black lesions tested positive for myeloperoxidase (MPO), cluster of differentiation (CD) 117, CD 3, CD 20, CD 15, multiple myeloma (MUM) 1, CD 68, and CD 138 and negative for CD 34 (Figure 5). Hence, the final diagnosis was ACA with myelolipomatous metaplasia.

(b)

Figure 1. (a) Result from the first ultrasonography showed a $7 \times 6 \text{ cm}^2$ mass that was suspected to originate from the liver in October 2014. (b) Image from the second ultrasonography in February 2015 showed that the size of the mass increased ($9 \times 7 \text{ cm}^2$). After the examination, the tumor was suspected to originate from the suprarenal region.

Figure 2. Result of the computed tomography scan revealed a hypervascular mass in the right adrenal gland with early washout enhancing pattern.

Figure 5. Immunohistochemistry staining results showing cytoplasmic and cell membrane positivity. (a) Inhibin (400×), (b) NSE (400×), (c) WT1 (400×) and (d) S100 (400×). The brown-black lesions showed (e) cytoplasmic positivity for MPO (400×) and (f) negativity for CD 34 (400×).

DISCUSSION

ACA is a rare type of tumor. Myelolipoma within an ACA is even an extremely rare condition. In 2008, only 17 cases of such condition were reported globally. Thirteen of the patients were women with a mean age of 45 years, and the youngest patient was aged 16 years. In general, ACAs have a predilection for woman, and it can occur in any age groups. Moreover, its incidence is equally distributed in both glands. In this case, a 40-year-old male patient presented with right adrenal lesion. No clinical findings, such as hypertension, hypokalemia, or hormonal imbalance, were observed. Hence, it was suspected as benign and non-functional adrenal lesion [4-9].

The widespread use of imaging has resulted in the increasing diagnosis of adrenal incidentaloma, which is an incidental mass. The World Health Organization defined this lesion as an adrenal mass that is identified serendipitously via radiologic examination in the absence of symptoms and clinical findings indicative of adrenal diseases. Imaging procedures can help in the localization of adrenal cortical adenoma. ACAs account for most adrenal masses incidentally found on CT scan in patients with indications other than suspected adrenal pathology and are typically characterized by a well-defined, round homogenous mass. The primary goal of imaging is to distinguish adrenal adenoma, adrenal carcinoma, pheochromocytoma, and metastatic lesions. The lesion in the abdomen of the patient incidentally found. First, the tumor was suspected as a hepatic carcinoma. However, based on

CT scan, which showed a heterogeneous with fine demarcated mass located in the suprarenal region, the physician then suspected the lesion as ACA [1, 5, 6, 10-14].

In the present study, the initial size of the mass was 7x6 cm. After 4 months, the size increased to 9 × 7 cm. The urologist then performed adrenalectomy. According to the American Association of Clinical Endocrinologists and American Association of Endocrine Surgeons (AACE/AAES) medical guidelines for the management of adrenal incidentalomas published in 2009, adrenalectomy after hormonal evaluation is the treatment option for a suspected malignant or indeterminate mass that is ≥ 4 cm on CT scan (Figure 6). Hormonal evaluation was not indicated in this patient due to the lack of obvious clinical signs [13, 15-17].

From the view of a pathologist, a differential diagnosis of a solid adrenal lesion include commonly diagnosed lesions (such as adenoma and pheochromocytoma) and uncommon lesions (including oncocytoma, ganglioneuroma, adrenal/peri-adrenal schwannoma, lipoma, and mature teratoma). We should also accurately differentiate benign lesions from adrenocortical carcinomas due to the fact that the prognosis, follow-up, and therapeutic strategy for ACC are different from those of a benign tumor [2, 14, 18].

The Weiss system is a method widely used to distinguish ACC from benign cortical tumor, including adenoma. The system was established in 1984 and included the following nine-point histopathological criteria: high nuclear grade, more than 5 mitoses per 50 high-power fields, atypical mitotic figures, with $< 25\%$ of tumor cells are clear cells, diffuse architecture (more than 33% of tumors), necrosis, venous invasion (smooth muscle in the wall), sinusoidal invasion (no smooth muscle in the wall), and capsular invasion. The presence of three or more criteria highly correlates with subsequent malignant behavior. In this case, only two criteria were observed, and $< 25\%$ of tumor cells were clear cells. Moreover, there were 10 mitoses per 50 high-power fields. Thus, based on the Weiss criteria, the adrenal lesion may be a benign lesion [1, 2, 6, 12].

Most ACAs are well-circumscribed intra-adrenal tumors, and some are encapsulated. Hemorrhage and necrosis are rarely observed. They can be tan-to -brown or bright yellow in appearance. Gross specimens obtained from oncocytoma are well-circumscribed adrenocortical lesions with dark tan-to-mahogany brown appearance (which is similar to other oncocytic lesions). They are large in size from 3 to 17 cm. Ganglioneuroma is an encapsulated mass with a solid, homogenous gray-white cut surface. Their size can reach up to 18 cm, and their consistency may range from gelatinous to solid. An adrenal/peri-adrenal schwannoma often appears as a solitary, well-circumscribed tumor enveloped in a fibrous capsule with a solid firm white-tan and homogenous cut surface that may contain cystic changes or hemorrhagic regions. Lipoma appears as a well-circumscribed tumor with a homogenous yellowish cut surface indicative of fat tissues. A mature teratoma showed a neoplasm indicating a mature tissue from the endoderm, mesoderm, and/or ectoderm. Lesions may be malignant if they had a coarsely lobulated appearance, with soft, bulging nodules ranging from yellow- orange to tan in color. A high number of areas with necrosis and hemorrhage are commonly observed. Examination of the gross specimen in this case revealed a rounded capsulated mass with fine demarcated outline, most of which appeared yellow with some of hemorrhagic areas and black-to-brown lesions on the cut surface. However, no necrosis was found. These findings were indicative of benign lesions, most probably an adrenal adenoma [1,6,19].

Figure 6. Algorithm for the evaluation and management of an adrenal incidentaloma according to the guidelines of the American Association of Clinical Endocrinologists and American Association of Endocrine Surgeons [13].

The definitive diagnosis of ganglioneuroma and schwannoma can be obtained via microscopic examination. Ganglioneuroma showed an area of Schwann cells with wavy dark nuclei and inconspicuous nucleoli with scant spindled cytoplasm, admixed with mature ganglion cells and eosinophilic cytoplasm, large vesicular nuclei, and prominent nucleoli. Oncocytomas have mitochondriac-rich cells with abundant compact eosinophilic cytoplasm that is finely granular. Adrenal/peri-adrenal schwannomas are microscopically identical to schwannomas found at any other anatomical sites. Spindle cells with alternating areas of compact hypercellularity with irregular streams and elongated spindle cells (Antoni type A) and of loosely-textured hypocellularity with cystic spaces (Antoni type B). In addition, Verocay bodies between the regions of nuclear palisades and thick walled hyalinized blood vessels may be observed. Mature teratomas are also microscopically identical with teratoma found elsewhere. The diagnosis of mature teratoma can be made if there is a minimum of two mature components observed from the endoderm (respiratory or digestive tract), mesoderm (fat tissue), or ectodermal (skin, bones, and chondrous tissue) without any immature component. ACAs consist of clear cells with abundant intracytoplasmic lipid droplets and compact cells with lipid sparse eosinophilic cytoplasm. These cells form cords and/or nests with relatively abundant vasculature or sinusoidal structures. The microscopic findings from this case were a fine demarcated lesion with mixture of clear and compact cells with eosinophilic cytoplasm indicative of adrenal adenoma and focal areas with myeloid and lipid component indicative of a myelolipoma metaplasia [1, 6, 7, 16, 19].

Table 1. Summary of the immunohistochemical staining confirming the adrenal tissues in this case and comparing them with the reference (+: positive, -: negative, n/a: not available) [7, 9-13]

Immunohistochemistry	ACA	Schwannoma	Ganglio-neuroma	ACC	Present case
S-100	+	+	+	+	+
Synaptophysin	+	–	+	+	+
CD-56	+	–	+	+	+
NSE	+	–	+	–	+
Laminin	–	+	–	–	n/a
Collagen IV	–	+	–	–	n/a
Desmin	–	–	–	–	n/a
CD-34	–	–	–	–	–
Keratin	+	–	–	+	+
Actin	+	–	–	+	n/a
Calretinin	+	–	–	+	+
Inhibin	+	–	–	+	+
Bcl-2	+	–	–	–	n/a
Melan-A	+	–	–	+	+

For further confirmation of the diagnosis of solid adrenal lesions, immunohistochemistry examination was conducted. According to Dabbs *et al.*, stainings for markers, such as inhibin A, WT1, and AE 1/3, can be used to confirm of the lesion originated from the adrenal tissues. To distinguish a benign from a malignant lesion, Jia *et al.* have recommended NSE staining as it shows positivity in the cell membrane and cytoplasm. Staining was also performed to confirm that the brown-black lesions observed in the macroscopic examination were myeloid component. The stainings were positive for MPO, focal positive for CD 117, CD 3, CD 20, CD 15, multiple myeloma (MUM) 1, CD 68, and CD 138, and negative for CD 34. The results are depicted in Table 1 [7, 8, 17].

The adrenal gland may present with different metaplasias that can be observed during microscopic examination. Occasionally, we can find lipomatous foci or bone cell metaplasia and even ovarian thecal metaplasia inside the glands. In this case, we found foci of myelolipomatous metaplasia within ACA. The causes of such metaplasia are not fully elucidated. Currently, the most accepted theories were embolization of the bone marrow, embryonic primitive mesenchymal cells, dysregulation of hematopoietic cell apoptosis, and adrenal response to stimuli, such as necrosis, infections, and stress [4, 20, 21].

The overall prognosis of surgically resected ACAs is good. Jia *et al.*, have reported no recurrences and metastases in any of the benign cases. The incidence rate of a benign adenoma developing into an ACC is not well known. However, such phenomenon is extremely rare [2, 11, 13].

CONCLUSION

A 40-year-old male patient presented with an incidental mass in the abdomen. The size of the mass increased within 4 months of diagnosis. The patient was then diagnosed with ACA

with myelolipomatous metaplasia by Hematoxylin & Eosin staining combined with immunohistochemistry staining. ACA is a rare type of tumor. Myelolipomatous metaplasia within an adenoma of the adrenocortex is an extremely rare finding. The correlation between clinical, radiological, and pathological examination results must be assessed to obtain a more accurate diagnosis. The pathogenesis of myelolipomatous metaplasia is still not fully elucidated.

ACKNOWLEDGMENTS

We would like to thank Evelina Kodrat, MD as pathologist who discovered the case and permitted the case to be reported. Nonetheless, thank you for my seniors and beloved fellow residents for the abundant support and encouragement.

ABSTRACT

Chronic myeloid leukemia (CML) is a myeloproliferative neoplasm of the hematopoietic stem cells, in which granulocytes are the major proliferative component. It is characterized by the chromosomal translocation between chromosomes 9 and 22, resulting in the *BCR-ABL1* fusion gene. *The clinical manifestation, bone marrow features, and laboratory test results at the time of diagnosis vary among reported patients and depend on the phase of CML.* Approximately 50% of newly diagnosed cases are asymptomatic and discovered when an abnormal white blood cell count is detected. In some cases, the bone marrow shows variable stages of fibrosis, whereas severe reticulin fibrosis is rarely observed. In this article, we present a patient with uncommon initial features of CML (i.e., pancytopenia, severe bone marrow fibrosis, and the absence of splenomegaly). Histopathological examination of the bone marrow revealed a hypercellular bone marrow with a normal myeloid to erythroid ratio showing myeloid maturation into segmented neutrophils. The number of megakaryocytes with atypical nuclei was increased, forming a cluster. Reticulin staining showed that fibers were increased diffusely and densely with extensive intersections. This increasing number of megakaryocytes and excessive fibrosis resembles primary myelofibrosis. The presence of the *BCR-ABL1* fusion gene confirmed the *diagnosis* of CML. The aim of this report is to share the experience of diagnosing a case of CML with a rare initial clinical course and excessive fibrosis of the bone marrow.

INTRODUCTION

Chronic myeloid leukemia (CML) is an acquired myeloproliferative neoplasm, in which granulocytes are the major proliferative component. It arises in hematopoietic stem cells and is associated with chromosomal translocation between the *ABL1* gene of chromosome 9 and the *BCR* gene of chromosome 22. This results in the formation of the Philadelphia (Ph) chromosome [1]. The translocation leads to the production of an abnormal tyrosine kinase enzyme, which causes excessive proliferation and reduced apoptosis in myeloid cells [2, 3]. Notably, the etiology of CML is unknown in most cases. There is an assumption that high-dose ionizing radiation may be linked to an increased incidence of CML. However, most CML cases reported thus far were not exposed to radiation [4].

The incidence of CML varies among countries, ranging from 0.4/100,000 individuals in non-Western countries to 1.75/100,000 individuals in the USA [4]. It can occur in all age groups; however, it is predominantly reported in middle and old age, accounting for 20% of adult leukemia cases [5]. The median age at the time of diagnosis is 57-60 years. CML is very rare in children. The male to female ratio is 1.2-1.7:1 [4]. From 2013 to 2016, a total of 41 cases of CML were diagnosed in the Anatomical Pathology Department of the Faculty of Medicine of Cipto Mangunkusumo Hospital, Jakarta, Indonesia. All patients were adults, with most cases reported in fifth decade of life.

CML is characterized by the increased and unregulated proliferation of myeloid cells without loss of their capacity to differentiate [6]. Cells in the myeloid cell line are those arising from myeloid progenitor cells, eventually becoming mature blood cells. These mature blood cells include basophils, neutrophils, eosinophils, monocytes, erythrocytes, and platelets. Although *BCR-ABL1* is found in all myeloid lineages, the initial major finding suggestive of CML is neutrophilic leukocytosis. The *BCR-AB1* translocation may also be found in *some lymphoid and endothelial cells*. *Of note, this translocation is found in 10% of patients with acute lymphoblastic leukemia* [1, 7].

In the USA, CML is diagnosed asymptotically or incidentally in 40-50% of patients. The condition is often diagnosed following a routine physical examination or blood test. White blood cell counts are increased, and the cells are differentiated and mature [8]. Common signs and symptoms of the chronic phase (CP), usually resulting from anemia and splenomegaly [2], include fatigue, weight loss, malaise, and left upper quadrant fullness or pain [1].

Based on the number of immature white blood cells (blasts cells) observed in the blood or bone marrow as well as other characteristic criteria, CML can be classified into three phases. These phases are important for prognosis and treatment [1]. The phases are CP, the accelerated phase (AP), and the blast phase (BP). The vast majority (90-95%) of patients are diagnosed during the CP, which is the earliest *phase of CML* [2]. The median duration of the CP is 5-6 years and, if left untreated, the disease usually progresses to the AP or BP. The duration of the AP and BP is 6-9 months and 3-6 months, respectively. The BP is the terminal phase of CML [9]. Approximately 30% of patients with CML present with marrow fibrosis, commonly mild or moderate. Notably, advanced bone marrow fibrosis occurs in <5% of

patients [10]. In general, almost all myeloid neoplasms have the potential to induce fiber deposition. Although the highest fibrotic risk is related to an underlying *BCR-ABL1*-negative primary myelofibrosis, it may also be found in *BCR-ABL1*-positive CML [11]. Rarely, CML may present with an unusual profile, rendering the diagnosis challenging [12]. CML may present with excessive bone marrow fibrosis and atypical presence of megakaryocytes, potentially resembling primary myelofibrosis [13, 14].

The aim of this report was to share the experience of diagnosing CML with unusual features, such as pancytopenia and atypical megakaryocytes with excessive fibrosis of the bone marrow. Targeted therapy against CML leads to life-saving remission. Therefore, it is very important to recognize CML at the time of initial diagnosis. In this case, the patient was diagnosed by the presence of the BCR-ABL fusion gene along with results obtained through clinical, laboratory, and histopathological examinations.

CASE REPORT

A 50-year-old male visited Siloam Hospital (Jakarta, Indonesia) in July 2017 with complaints of generalized body weakness, which worsened in the previous 5 days. Dizziness and blurred vision were noted. The patient had a history of two blood transfusions performed in May 2017 in Manado, Indonesia. His vital signs were normal and there was no palpable organomegaly in his abdomen. Laboratory tests, including a complete blood count, were conducted and the results revealed anemia and leukopenia. Therefore, the patient was advised to undergo *bone marrow aspiration and biopsy*.

In August 2017, the patient returned to the same hospital with similar complaints. The laboratory results showed pancytopenia with differential cell count, low blast cell count, and normal segmented neutrophils count (Table 1).

Table 1. Results of the laboratory blood test

Tests	Result, July 2017	Result, August 2017	Unit	Reference interval
Hemoglobin	6.5	3.7	g/dL	13.0-18.0
Hematocrit	18.5	10.4	%	40.0-54.0
Erythrocytes	2.25	1.36	10 ⁶ /μL	4.50-6.20
MCV	82.2	76.5	fL	81.00-96.00
MCH	28.9	26.5	pg	27.0-36.0
MCHC	35.1	14.6	g/L	31.0-37.0
White blood cells (WBC)	2.6	1.0	10 ³ /μL	4.00-10.00
Differential count				
Basophils	0		%	0-1
Eosinophils	0		%	0-4
Band neutrophils	2		%	2-6
Segmented neutrophils	62		%	50-70
Lymphocytes	27		%	20-40
Monocytes	7		%	2-8
Platelets	268	77	10 ³ /μL	150-400

His pancytopenia was managed mainly through the transfusion of red blood cells and platelets. The level of lactate dehydrogenase in the serum was increased. The liver function test, and the levels of creatinine, bilirubin, and electrolytes were within the normal range. *Chest* radiography showed pneumonic infiltration. Ultrasonography of the abdomen and pelvis revealed a slightly enlarged liver with homogeneous parenchyma. The spleen, bladder, and prostate were normal.

The results of the bone marrow aspiration showed a myeloid to erythroid ratio within the normal range (Table 2). Maturation in the myeloid series presented into segmented neutrophils and the number of blasts was not elevated.

A review of the bone marrow biopsy was also performed at Cipto Mangunkusumo hospital. A histopathological examination revealed a hypercellular bone marrow (Figure 1 a, 1 b) with a normal myeloid to erythroid ratio, showing myeloid maturation into segmented neutrophils (Figure 2 a, 2 b). In addition, the number of megakaryocytes with atypical nuclei was increased, forming a cluster (Figure 3 a, 3 b).

Table 2. Bone marrow aspiration performed in July, 2017

Tests	Result	Unit	Reference interval
Thrombopoiesis			
Megakaryocytes count	-		
Myeloid series			
Myeloblasts	0.0	%	0-1
Promyelocytes	1.0	%	1-5
Myelocytes	0.0	%	2-10
Metamyelocytes	2.0	%	5-15
Bands	2.0	%	10-40
Segmented neutrophils	29.0	%	10-30
Basophil	0.0	%	0-1
Eosinophil	0.0	%	0-3
Myeloid total	34	%	
Erythroid series			
Pro-erythroblasts	0.0	%	0-1
Erythroblasts basophils	0.0	%	1-4
Polychromatic erythroblasts	6.0	%	10-20
Orthochromatic erythroblasts	7.0	%	5-10
Erythroid total	13.0	%	
Male to female ratio	2.6:1	%	(2-4):1
Other series			
Lymphocytes	40	%	0-15
Monocytes	7	%	0-2
Plasmocytes	6	%	0-1

Staining with Periodic Acid Schiff (PAS) showed that the number of megakaryocytes was increased. Some megakaryocytes were scattered with small, hypolobated nuclei (Figure 4 a, 4 b). Reticulin staining showed that the fibers were increased diffusely and densely with extensive intersections (Figure 5 a, 5 b). Trichrome staining showed the presence of focal bundles of collagen fibers (Figure 6 a, 6 b). According to the definition established by the World Health Organization, the grade of marrow fibrosis was marrow fibrosis 3. Hence, this

patient was diagnosed with a myeloproliferative neoplasm, suggestive of primary myelofibrosis.

Figure 1. (a, b) Bone marrow biopsy showed a hypercellular bone marrow (H&E, 40×, 100×).

Figure 2. (a, b) Higher magnification revealed a normal myeloid to erythroid ratio, showing myeloid maturation into segmented neutrophils. The number of blasts was not increased (H&E, 400×).

Figure 3. (a, b) The number of megakaryocytes with atypical nuclei was increased, forming a cluster (H&E 400×).

Figure 4. (a, b) Increased megakaryocytes. Some scattered megakaryocytes were small with hypolobated nuclei (PAS, 40×).

Figure 5. (a) Reticulin fibers were increased diffusely and densely (Reticulin, 4×). (b) Extensive intersections of reticulin fibers (Reticulin, 40×).

Figure 6. (A-B) The bone marrow exhibited focal bundles of collagen fibers (Trichrome, 10×).

Subsequently, an evaluation of mutations in the JAK2 gene and the presence of the BCR-ABL1 fusion gene was performed using blood samples to reach a definitive diagnosis.

The presence of the BCR-ABL1 fusion gene was determined through real-time quantitative polymerase chain reaction. The analysis for mutations in the JAK2 gene yielded negative results. The presence of the BCR-ABL1 abnormality confirmed the diagnosis of

CML in this patient. Based on the presence of excessive bone marrow fibrosis and thrombocytopenia (unrelated to therapy), CML at that time was considered to be at the AP.

This patient exhibited uncommon clinical, laboratory, and morphologic bone marrow features to meet the criteria for the diagnosis of CML. In this, case the condition included pancytopenia, absence of splenomegaly, and excessive bone marrow fibrosis, with some megakaryocytes showing atypical nuclei. Owing to the uncommon clinical features, this patient also consulted a pathologist in Germany. He preferred to diagnose this case as CML because of the presence of the *BCR-ABL1* fusion gene. The treating physician had previously encountered a number of similar CML cases with excessive fibrosis and the absence of an increase in size of the spleen. In this case, the majority of megakaryocytes exhibited atypical nuclei. However, a number of megakaryocytes exhibited the “dwarf form,” which is typical in CML.

DISCUSSION

The clinical hallmark of CML is leukocytosis, i.e., the uncontrolled production of maturing granulocytes including neutrophils, basophils, and eosinophils in the peripheral blood [15]. Of note, the number of platelets is normal or slightly increased and mild to moderate anemia is usually noted. In our case, the initial peripheral blood findings revealed pancytopenia. The patient had abnormally low levels of red blood cells, white blood cells, and platelets. This condition may be the result of myelofibrosis, which accompanies CML [14]. Myelofibrosis is the presence of reticulin and deposition of collagen, replacing bone marrow hematopoietic cells with fibrous material. The exact pathogenesis of myelofibrosis is not fully understood. However, evidence has demonstrated the role of activating mutation involving *CALR*, the deregulated expression of pro-inflammatory cytokines, and the impaired bone marrow microenvironment [6].

The bone marrow microenvironment is composed of cells, structural fibrils, and the extracellular matrix. The cellular components include macrophages, fibroblastic cells, adipocytes, and endothelial cells. The most common structural fibrils in the bone marrow are collagen and reticulin. The ground substance includes water, salts, glycosaminoglycans, and glycoproteins. These elements provide a connective tissue structure for the bone marrow and physical support for the hematopoietic progenitor cells. Consequently, the bone marrow microenvironment plays an important role in hematopoiesis [12].

The elevation of pro-inflammatory cytokines is a major biological hallmark of bone marrow fibrosis. This effect is thought to be a consequence of the malignant clone as a modifier of the bone marrow microenvironment. One neoplastic cell type thought to be a major contributor to fibrosis is the megakaryocyte, which exhibits aberrant proliferation [11]. Megakaryocytes produce the transforming growth factor β . This cytokine potently stimulates fibroblasts to produce the extracellular matrix. Moreover, it increases the expression of proteases that inhibit enzymes involved in the degradation of the extracellular matrix [6]. Hence, megakaryocytes are important mediators in the development of bone marrow fibrosis [12].

Table 3. Phases of chronic myeloid leukaemia according to WHO

CML phase	WHO definition
Chronic phase (CP)	- Peripheral blood (PB) shows leukocytosis ($12-1000 \times 10^9/L$) - Blasts less than 2% of the white blood cells (WBC) - Basophilia is invariably present, eosinophilia is common - Monocytosis may be present, but usually $<3\%$ - Platelet ranges from normal to greater than $1000 \times 10^9/L$, thrombocytopenia is uncommon. - Bone marrow cellularity is increased - Blasts account $< 5\%$ of the marrow cells - Erythroid islands are usually reduced - Megakaryocytes may be normal or slightly decreased in number, 40-50% exhibit moderate to marked proliferation. - Megakaryocytes are smaller than normal and have hyposegmented nuclei (dwarf megakaryocytes) - Moderate to marked reticulin fibrosis correlates with increased numbers of megakaryocytes and associated with an enlarged spleen was found in 30-40% of biopsies
Accelerated phase (AP)	Presence of ≥ 1 of the following hematological/cytogenetic criteria or provisional criteria concerning the response to therapy with tyrosine kinase inhibitors (TKIs). Hematological/cytogenetic criteria: - Persistent or increasing WBC ($>10 \times 10^9/L$), unresponsive to therapy - Persistent or increasing splenomegaly, unresponsive to therapy - Persistent thrombocytosis ($>1,000 \times 10^9/L$), uncontrolled by therapy - Persistent thrombocytopenia (unrelated to therapy) - Basophil $\geq 20\%$ in the PB - 10-19% blasts in the PB or bone marrow
Accelerated phase (AP)	- Additional clonal chromosomal abnormalities in the Philadelphia (Ph) chromosome, including major route abnormalities (a second Ph chromosome, trisomy 8, isochromosome 17q, and trisomy 19), a complex karyotype, and abnormalities of 3q26.2 - Any new clonal chromosomal abnormality in Ph⁺ cells that occurs during therapy - Criteria for the provisional response to TKIs - Hematological resistance (or failure to achieve complete hematological response) to the first TKI - Any hematological, cytogenetic, or molecular indication of resistance to sequential treatment with two TKIs - Occurrence of at least two mutations in the <i>BCR-ABL1</i> fusion gene during TKI therapy. Large clusters or sheets of small, abnormal megakaryocytes with marked reticulin or collagen fibrosis
Blast phase	- Blasts $\geq 20\%$ of the PB WBC, or of the nucleated cells of the bone marrow - Extramedullary blast proliferation

In our case, the predominance of fibrosis and atypical megakaryocytes at presentation confounded the initial diagnosis. This raised the possibility of a differential diagnosis, such as primary myelofibrosis. Mohamed et al. reported a CML case with advanced myelofibrosis

resembling primary myelofibrosis. That case also presented with anemia, thrombocytopenia, and an absence of splenomegaly; however, the white blood count was within the normal range. Therefore, it is recommended that a molecular analysis is performed in patients with myelofibrosis [10].

In patients with CML, various grades of megakaryocytic proliferation can be observed in bone marrow biopsies or cytological smears at the time of diagnosis [15]. CML with marrow fibrosis is more commonly developed in patients with a marked megakaryocytic proliferation [10]. In our case, the histopathological examination of the bone marrow through reticulin staining showed that fibers were increased diffusely and densely with extensive intersections. This finding was consistent with the observed increase in the number of megakaryocytes. This case presented with advanced (grade 3) fibrosis.

CML is classified into three phases that assist in predicting the prognosis. The phases are determined mainly according to the number of immature white blood cells (blasts cells) observed in the blood or bone marrow (Table 3) [1].

The recognition of disease progression, during which the CP develops into the AP and BP, is important for treatment and prognostic purposes. Unfortunately, the clinical and morphological differences between the CP, AP, and BP are not always clear. Large clusters or sheets of small, abnormal megakaryocytes with marked reticulin or collagen fibrosis are suggestive of AP, especially if accompanied by any of the hematological parameters [1]. In our case, the number of megakaryocytes with atypical nuclei was increased, forming a cluster. In addition, thrombocytopenia (unrelated to therapy) was noted. These findings are indicative of the AP.

In the CP, splenomegaly is observed in approximately 70% of CML patients, caused by the infiltration of the red pulp cords by mature and immature granulocytes [1]. In the AP and BP, splenomegaly is due to extra-medullary hematopoiesis. This patient did not exhibit splenomegaly.

The diagnosis of CML is based on the detection of the *BCR-ABL1* fusion gene, which is the underlying abnormality of this disease [12]. This mutation leads to persistently enhanced tyrosine kinase activity. This activity is responsible for maintaining proliferation and inhibiting differentiation and apoptosis. This leads to an excessive number of neoplastic clones in the bone marrow. Furthermore, neoplastic cells replace non-neoplastic hematopoietic and mesenchymal cells (adipocytes) [14]. The real-time quantitative polymerase chain reaction is used to detect the presence of the *BCR-ABL1* mutation. It can detect a single CML cell in 100,000 normal cells isolated from blood or bone marrow samples [16]. The results of this test are reported using the international scale. This analysis was performed in the present patient, showing positivity for *BCR-ABL1*, with 6% on the international scale.

CONCLUSION

CML is an acquired myeloproliferative neoplasm, in which granulocytes are the major proliferative component. It develops in hematopoietic stem cells and is characterized by a chromosomal translocation, resulting in the *BCR-ABL1* fusion gene and the formation of the Ph chromosome. The majority of CML cases are diagnosed on the basis of findings in the

peripheral blood and bone marrow biopsy, combined with the detection of the Ph chromosome. Rarely, a number of CML cases exhibit atypical peripheral blood test results and uncommon histopathological features in the bone marrow biopsy, resembling primary myelofibrosis in the overt fibrotic stage. Therefore, the diagnosis of CML should not be immediately excluded prior to confirming the presence of the Ph chromosome or *BCR/ABL1* rearrangement.

The diagnosis of CML with atypical features (i.e., pancytopenia and excessive fibrosis of the bone marrow) requires the combination of clinical, laboratory, and histopathological examinations, accompanied by the presence of an acquired genetic abnormality, the *BCR/ABL1* fusion gene. An increased awareness of this disease, especially at the CP, may prevent progression to the AP or BP.

ABSTRACT

Clear cell chondrosarcoma is a rare variant of low-grade malignant cartilaginous tumor, representing approximately 2% of all chondrosarcomas. In this article, we report a rare case of clear cell chondrosarcoma in a 21-year-old male. Histopathological findings showed abundant clear cytoplasm or a faintly acidophilic cytoplasm with distinct cytoplasmic borders. The nuclei were round, vesicular, and centrally located, with prominent nucleoli. Mitotic figures are uncommon. Follow-up immunohistochemical staining showed positivity for S-100 protein and negativity for other epithelial markers, supporting the diagnosis of clear cell chondrosarcoma. Clear cell chondrosarcoma mostly involves the epiphyseal of long bones, especially in the femur or humerus. Complete surgical excision is the treatment of choice.

Keywords: chondrosarcoma, clear cell chondrosarcoma

INTRODUCTION

Clear cell chondrosarcoma is a rare variant of low-grade malignant cartilaginous tumor, representing approximately 2% of all chondrosarcomas [1]. Unni et al. first described it in 1976, the clear cell chondrosarcoma entity was formerly known as “Clear-cell Variant of Chondrosarcoma” [2,3]. The cytoplasm appears clear due to the abundance of glycogen in tumor cells [1,4]. This condition tends to arise in the epiphyseal area of long bones [1,4-6]. The peak incidence is observed during the third and fourth decades of life [4].

We report this case to avoid the risk of inaccurate diagnosis and recognize the differential diagnosis.

CASE REPORT

A 21-year-old male had a chief complaint of pain ranging from knee up to left hip for almost 2 years and 4 months. The patient then underwent pelvic X-ray and lumbosacral *magnetic resonance imaging* (MRI) examination. The Pelvic X-ray showed an expansile lytic lesion with a wide transition zone on the left proximal femoral. There was no cortical destruction, presence of a soft-tissue mass, or periosteal reaction (Figure 1). MRI results showed lesions that destructed the left femoral head and also appeared a signal with the same intensity as lesions in the surrounding soft tissue and left hip joint (Figure 2.). These findings indicated the presence of an aggressive primary bone tumor.

Figure 1. Pelvic X-ray examination showed the presence of an expansile lytic lesion with a wide transition zone. There was no cortical destruction, presence of a soft-tissue mass, or periosteal reaction (arrow).

Later, the patient underwent an open biopsy of his left femoral head at a hospital. Histological report revealed fragments of lesional tissue, comprising cellular nests of polygonal cells with central nuclei, conspicuous nucleoli, and pale eosinophilic to clear cytoplasm, admixed with small trabeculae of new reactive bone. Scattered multinucleated giant cells were present. In other area of the tumor, small foci resembling conventional chondrosarcoma were present. The tumor cells were immunoreactive for S-100 but negative for MNF116. These results were consistent with clear cell chondrosarcoma.

After one month, the patient underwent a wide excision procedure in another private hospital. The specimen from wide excision was sent to the laboratory of anatomic pathology. By report, the histopathological features showed a solid tumor mass with formation of a malignant osteoid. The tumor cells consisted of chondroblastic and epithelioid cells with pleomorphic and hyperchromatic nucleoli. Mitotic activity was easily observed. Osteoclast-

Figure 2. Coronal (a) and axial (b) lumbosacral MRI. The MRI results showed lesions that destructed the left femoral head and also appeared a signal with the same intensity as lesions in the surrounding soft tissue and left hip joint. These findings indicated the presence of an aggressive primary bone tumor.

Due to the differences in histological results, this case was discussed at our weekly Clinicopathological Conference (CPC) and suggested to repeat immunohistochemical staining on resection specimen as we were not able to have the slides and paraffin block from the first open biopsy. Based on the slides provided, the histological appearance under low magnification showed that the solid mass consisted of bony trabeculae, with osteoblastic rimming among the tumor cells. The tumor cells were round, with slightly-moderately pleomorphic nuclei; there were large cells with distinct cytoplasmic borders in several areas, prominent nucleoli, and abundant clear or pale eosinophilic cytoplasm. Mitotic activity was infrequent. Multinucleated giant cells and production of cartilage matrix were also visible (Figure 3-6). The repeated immunohistochemical staining results showed that the neoplastic cells were positive for S-100 (Figure 7) and negative for AE1/3, CK8, CK18, CK7, and CK20. These morphological and immunohistochemical staining features were consistent with clear cell chondrosarcoma.

Figure 3. The solid mass consisted of bony trabeculae, with osteoblastic rimming among the tumor cells (arrow). Production of cartilage matrix was also found (arrow head)(H&E, ×40).

Figure 7. The nuclei of neoplastic cells were positive for the S-100 protein (H&E, $\times 400$).

DISCUSSION

Clear cell chondrosarcoma is a rare variant of chondrosarcoma [1]. It mostly occurs in adults (third to fifth decades of life) with a 2.4:1 male-to-female ratio [1, 4]. The initial symptom is local pain in the affected area, developing in the longterm due to the slow growth of the tumor [1, 2, 4, 6]. Our patient was a 21-year-old male, who had been suffering from pain on his left knee for 2 years prior to his admission to the hospital.

Clear cell chondrosarcoma usually involves the epiphysis of long bones, especially the femur or humerus [1, 4]. Chondroblastoma and GCT of the bone exhibit similar localization with clear cell chondrosarcoma, whereas conventional chondrosarcoma is usually found in the metaphysis or diaphysis of long bones [5].

Clear cell chondrosarcoma is characterized by a distinctive histologic feature i.e., the presence of “clear cells” (abundant clear to faintly acidophilic cytoplasm with distinct borders), whose nuclei are large, vesicular, and centrally located. The nucleoli are usually prominent and mitotic figures are uncommon [1-6]. Histologically, it may resemble chondroblastoma, GCT of the bone, osteoblastoma, or even conventional osteosarcoma [5].

The most common radiological of clear cell chondrosarcoma findings are well-margined radiolucent areas with distinct reactive borders, an absence of cortical destruction or periosteal reaction, and unusual soft-tissue extension [3,5,7]. The radiological findings of clear cell chondrosarcoma must be differentiated from those of other benign epiphyseal lesions, such as chondroblastoma and GCT of the bone [7-9]. In this report, the pelvic X-ray examination was an expansile lytic lesion with a wide transition zone. There was no cortical destruction, presence of a soft-tissue mass, or periosteal reaction.

Chondroblastoma arises in the epiphysis or epimetaphysis of long bones, more commonly in male and younger patients [10,11]. Radiologically, chondroblastoma is typically a small (3-6 cm), well-demarcated lytic lesion and generally with no bone expansion. Periosteal reaction is frequent and occasionally distant from the primary lesion [10]. Microscopically, the tumor cells are usually surrounded by fine lines of calcification, which are typical in both clear cell chondrosarcomas and chondroblastomas. However, chondroblastoma does not show a clear

cytoplasm, which is typical for clear cell chondrosarcoma. Instead, it shows an oval nucleus with a nuclear groove and a faintly acidophilic cytoplasm [2]. In general, the distinction between chondroblastoma and clear cell osteosarcoma do not necessarily require immunohistochemistry staining. However, in several difficult cases, SOX9 and cytokeratins are useful to distinguish both entities. The expression of SOX9 and cytokeratins is found in chondroblastoma, while it is negative in clear cell chondrosarcoma [10].

Moreover, GCT of the bone affects the same site as clear cell chondrosarcoma [5]. Notably, the radiological and histopathological features are evidently different from those observed for clear cell chondrosarcoma. GCT of the bone is usually found in patients aged 20-40 years, with a slight predominance observed in female patients [12,13]. Plain radiography of GCT showed a large expansile lytic-sclerotic lesion with cortical thinning (the “soap-bubble appearance”). The presence of numerous osteoclast-like giant cells, which contain >20 nuclei, is the hallmark of GCT [4,13,14]. In contrast, scattered multinucleated giant cells in clear cell chondrosarcoma are not associated with the neoplastic process, and they usually contain only 6-8 nuclei [5].

In addition, clear cell chondrosarcoma has a scattered osteoid matrix and a bony trabeculae appearance among the tumor cells resembling conventional osteosarcoma. Osteoid matrix with lace-like appearance and accompanied with an increase level of alkaline phosphatase in the serum prior to surgery should be considered as osteosarcomas, especially in young patients [5,9]. Radiographically, conventional osteosarcoma exhibits a permeative pattern with periosteal reaction, cortical destruction, and the extension of soft-tissue mass [4,15,16]. Meanwhile, clear cell chondrosarcoma exhibits a well-marginated radiolucent area with distinct reactive borders and an absence of cortical destruction [1,3,4]. Conventional osteosarcoma features high-grade nuclei, such as severe nuclear anaplasia and pleomorphism with occasional mineralization [15]. The absence of a clear cell population among the intertrabecular spaces and its location may distinguish osteosarcoma from clear cell chondrosarcoma [4,15].

The presence of an interanastomosing osteoid with osteoblastic rimming may also be considered as osteoblastoma. Osteoblastoma is composed of osteoblasts that are rich in vascularity. The absence of the clear cell feature distinguishes this tumor from clear cell chondrosarcoma [2,4,5,17].

The patient was initially diagnosed with clear cell chondrosarcoma based on histological report from the open biopsy specimen. He underwent wide excision at another private hospital with result showing conventional osteosarcoma. Due to the differences in histological results, the case was presented at CPC and was suggested to repeat the immunohistochemical staining to confirm the diagnosis. The immunohistochemical staining showed positivity for the S-100 protein and negativity for other epithelial markers (i.e., AE1/3, CK8, CK18, CK7, and CK20). The final diagnosis was clear cell chondrosarcoma.

Ancillary staining, such as histochemistry and immunohistochemistry, may assist in confirming the diagnosis of clear cell chondrosarcoma. The content of glycogen in the cytoplasm explains the clear cytoplasm feature and yields positive staining for periodic acid-Schiff [1,4,7]. The nuclei in clear cell chondrosarcomas are strongly positive for the S-100 protein [1,3,4,7,18,19]. Matsuura S et al. investigated the immunohistochemical expression profiles of cytokeratins (i.e., CAM5.2, AE1/AE3, CK7, CK8, CK18, and CK20), epithelial membrane antigen, sex-determining region Y-box 9 (SOX9), type II collagen, runt-related transcription factor 2 (RUNX2), and osteocalcin in clear cell chondrosarcoma. The results

were compared with those observed in chondroblastoma, conventional chondrosarcoma, and osteosarcoma. Both clear cell chondrosarcoma and chondroblastoma showed epithelial and chondrogenic markers. Clear cell chondrosarcomas stain negative for CAM5.2 and the epithelial membrane antigen. The type II collagen immunohistochemistry showed 100 % positivity in clear cell chondrosarcoma while in chondroblastoma showed positivity for about 54%. The cartilagenous component of clear cell chondrosarcoma and chondroblastoma express SOX9 respectively 20% and 54%. Osteocalcin is not detected in the cytoplasm of clear cells; however, it is expressed in osteoblasts and osteocytes within woven bone. RUNX2 up-regulated the promoter activity of osteocalcin in osteosarcoma cell lines, but not in chondrosarcoma or chondrocyte cell lines [19].

The treatment of choice for clear cell chondrosarcoma is a wide and complete surgical excision. Chondrosarcoma has a relatively low proliferation rate, thus, radiotherapy remains ineffective as it aims at actively dividing cells. Systemic treatments, such as chemotherapy, have also been shown to be ineffective [20].

Inappropriate treatment results in recurrence in 16% of patients. En bloc excision is preferable to marginal excision or curettage. Although clear cell chondrosarcoma is commonly considered an indolent tumor; however, lung, brain, and bone metastases have been reported. The average rate of mortality is approximately 10%, while disease-free survival after incomplete removal is 13 years. The overall survival rate in patients with metastasis after initial therapy is approximately 7 years [4].

CONCLUSION

Clear cell chondrosarcoma is a rare variant of low-grade malignant cartilaginous tumor, representing approximately 2% of all chondrosarcomas. Increased awareness regarding this disease may prevent misdiagnosis. Histologically, it may resemble other tumors, such as chondroblastoma, GCT, osteoblastoma, and conventional osteosarcoma. Immunohistochemical features are able to distinguish between the differential diagnoses. Clear cell chondrosarcomas are strongly positive for the S-100 protein. Sufficient clinical data, including location, radiological finding combined with microscopic features, and appropriate ancillary staining are mandatory to avoid misdiagnosis.

ABSTRACT

Hürthle cell carcinoma (HCC) of the thyroid is an unusual and relatively rare type of thyroid cancer. Small series of HCC patients have been reported in the literature, but because of its relative rarity, its pathological and clinical significance have not been well documented. A 55-year-old woman presented with rapid neck mass enlargement and hoarseness. Thorax X-ray imaging suggested intrathoracic struma. Ultrasonographic examination showed struma nodosa in the right lobe. Fine-needle aspiration biopsy results suggested a follicular neoplasm of Hürthle cell type. Grossly, the right thyroid size was 6 × 5 × 4 cm and was brown, firm, and encapsulated. The cut surfaces were brown and lobulated, with no papillary growth or calcification. A histological examination showed large tumor cells in a trabecular arrangement, rounded nuclei, coarse chromatin, some vesicular with prominent nucleoli, and abundant granular eosinophilic cytoplasm. Another section revealed capsular invasion, and a solid area containing scattered bizarre giant cells with irregular nuclei. The histopathological features and immunohistochemical staining results supported a diagnosis of encapsulated angioinvasive HCC with bizarre nuclei. HCC is a rare type of carcinoma that remains controversial and difficult to diagnose. Careful assessment should be performed to look for bizarre nuclei to prevent overdiagnosis.

Keywords: carcinoma, Hürthle cell, morphology, thyroid, unique

INTRODUCTION

Thyroid carcinoma is the most common endocrine malignancy. Most these cancers are derived from the follicular epithelial cells of the thyroid gland. The cancers are further divided into sub-groups, depending on the degree of differentiation, and range from well-differentiated thyroid carcinoma (WDTC) to rare undifferentiated (UTC) or anaplastic thyroid carcinoma (ATC) [1, 2].

Hürthle cell tumor (HCT) is a rare thyroid neoplasm of the follicular cell origin, with >75% being composed of cells with oncocyctic features. The ability to classify each tumor with oncocyctic features as either benign or malignant has remained controversial [3]. HCT has no specific imaging characteristics. Ultrasound alone is unable to distinguish Hürthle cell carcinoma (HCC) from other histological variants. There are preoperative and intraoperative difficulties in discriminating adenoma from carcinoma [4, 5]. Small series of HCC patients have been reported in the literature, but HCC is an understudied cancer with poor prognosis. Because of its relative rarity, its pathological and clinical significance have not been well documented [3, 6].

HCC of the thyroid gland is unusual. It accounts for only approximately 3%-10% of all differentiated thyroid cancers and has the highest incidence of metastasis among the differentiated thyroid cancers [7]. HCC has a more aggressive natural history than that of follicular carcinoma, with a higher rate of locoregional recurrence, distant metastases, and mortality [8]. In the last five years, we have registered nine cases of HCT in Cipto Mangunkusumo Hospital (CMH), which include one case of Hürthle cell adenoma (HCA), four cases of minimally invasive HCC, and four cases of HCC.

HCC is a malignant thyroid neoplasm composed of oncocytes derived from follicular cells crowded with mitochondria, which are also called Hürthle cells, Askanazy cells, or oxyphylic cells [9]. The behavior of Hürthle cell neoplasms is unpredictable [4]. Differentiation of HCA and HCC is performed based on capsular or vascular invasion and the presence of metastases [8]. The prognosis of the malignant types of these tumors remains debatable because some authors have reported that HCA occasionally behaves like HCC [3]. In many HCC, the amount of cytoplasm is less abundant than that in adenoma, which results in an increased nuclear/cytoplasm ratio. A greater percentage of cells are tall, cuboidal or columnar, and scattered bizarre hyperchromatic forms maybe seen only in the adenoma [9].

According to the literature, both benign and malignant thyroid lesions contain so-called "cells of endocrine atypia" or cells with bizarre nuclei. These manifest as single cells or small groups displaying marked cellular and nuclear enlargement, some degree of pleomorphism, marked cellular hyperchromasia, and occasionally macronucleoli randomly dispersed among otherwise differentiated thyroid follicular cells. The presence of these enormous cells can be extremely worrisome and should be carefully assessed to arrive at the correct diagnosis [10]. We describe a rare case of HCC with unique morphological features that were identified in CMH.

CASE REPORT

A 55-year-old woman came to CMH on July 21, 2014, with a chief complaint of neck mass enlargement for the previous 10 months (Figure 1). Her past medical history revealed that the patient had lived with a small nodule the size of a corn kernel in her right neck for the last 12 years but she did not have any nodule-related complaints. However, she noticed that the neck mass began enlarging and had reached the size of a chicken egg over the previous 10 months. She went to the doctor and began taking levothyroxine once a day. She had been taking the drug for one month but then felt exhaustion and experienced palpitation, so she stopped taking the medicine. She also became hoarse but did not feel any pain, experience dyspnea, or notice exophthalmus. She went to a primary health care facility and was then referred to the CMH Internal Medicine department with a diagnosis of toxic struma nodosa and hypertension. She began taking amlodipin 10 mg once a day. She had no history of diabetes mellitus (DM), asthma, or allergy. Her family medical history showed that the patient's father had a history of tumor, the mother had a carcinoma of the cervix, and a sibling had type II DM. The patient was managed in the CMH Internal Medicine department and was scheduled to undergo a fine-needle aspiration biopsy (FNAB) procedure, ultrasound examination, administration of thyroid-stimulating hormone (TSH), and free thyroxine (fT4) laboratory tests.

Figure 1. A lump in the right anterior of the neck that moved upward when swallowing. The lump had a diameter of 6 cm and a firm distinct border. The left lateral border was in the midline, the right lateral border was in the medial sternocleidomastoid muscle, the inferior border was in the sternal notch, and the superior border was in the hyoid bone.

Chest X-ray showed a soft tissue mass in the right inferior colli that pushed the trachea to the left and suggested intra-thoracic struma (Figure 2). Ultrasound examination of the right lobe showed an isoechoic, rounded heterogeneous lesion that was well demarcated with a regular edge and fully loaded the thyroid's right lobule. The lesion size was $3.7 \times 3.34 \times 3.3$ cm. Intra-lesion calcification was not seen. Doppler technique showed intra-lesion vascularization. The thyroid's left lobe was normal in size and shape, with no focal pathological lesion or calcification. A lesion with a solid and cystic component was seen in

the isthmus. The trachea was located in the midline. Lymph node enlargement was not found. Radiological examination identified a struma nodosa in the right lobe of the thyroid and an isthmus nodule (Figure 3). Laboratory examination showed normal sensitive TSH (sTSH) and fT4. The sTSH level was 1.210 μ IU/mL, and the fT4 level was 1.420 ng/dL.

FNAB was performed on August 14, 2014, and the results suggested a follicular neoplasm of Hürthle cell type. Then, the patient was sent to the CMH Surgical Oncology Department. The physical examination revealed a nodule in the right anterior of the neck that moved upward when the patient swallowed. The nodule had a size of approximately $5 \times 4 \times 3$ cm and a firm, mobile, smooth surface. The temperature was the same as that of the surrounding tissue. Jugular, submandible, and submental lymph nodes were not palpable (Figure 1).

On February 6, 2015, the patient underwent isthmolobectomy surgery. Her last laboratory tests showed a normal blood count, except for a differential count, and the routine biochemical blood test results were within normal ranges. Euthyroid state was confirmed by the laboratory result. The preoperative clinical diagnosis was struma nodosa non-toxic suspected as a malignant T3N0M0. Intraoperative pathological consultation using frozen sections supported a diagnosis of WDTC transformed to ATC. According to this result, the surgeon decided to perform a total thyroidectomy in this patient. Tissue samples were sent to the CMH Anatomical Pathology Department.

Figure 2. Chest X-ray image showing a soft tissue mass in the right inferior colli, suggesting an intrathoracic struma. The heart and lung were normal.

(a)

(b)

Figure 3. Ultrasound examination of the right lobe showing a rounded heterogeneous isoechoic lesion with a well-demarcated regular edge and that fully loaded the right lobule of the thyroid. The lesion size is 3.7 x 3.34 x 3.3 cm. Intralesion calcification is not seen.

Cytology Findings

FNAB smears contained diffuse clusters of large cells with abundant granular eosinophilic cytoplasm. These cells had pleomorphic nuclei, coarse chromatin, and some showed prominent nucleoli. There were scattered giant cells and multinucleated giant cells. More than 75% of the aspirate was composed of these oncocytic cells. The FNAB findings suggested a diagnosis of follicular neoplasm of the Hürthle cell type.

Macroscopic and Histologic Presentation

Grossly, the resected right thyroid measured $6 \times 5 \times 4$ cm and was brown to red, firm, and encapsulated. The surface was smooth, and the cut surface was brown and lobulated. Calcification and papillar growth were not seen (Figure 4). The left thyroid lobe measured $3 \times 1.5 \times 0.5$ cm and was brown to black and firm. The sentinel lymph nodes were also sent to the Anatomic Pathology Department.

Figure 4. Gross appearance. The thyroid size is approximately $6 \times 5 \times 4$ cm and is brown to red, firm, and encapsulated. The surface is smooth, and the cut surface is brown tinted and lobulated. Calcification and papillary growth are not seen.

Figure 5. Cytologic features of FNAB. (a, b) Dispersed cluster of epithelial cells with atypical enlarged nuclei and abundant eosinophilic (Giemsa stain, $10\times$). (c, d) The cells have granular eosinophilic cytoplasm (Papanicolaou stain A. $100\times$, B $400\times$).

Figure 6. Variable appearance of HCC. (a) The cells are arranged in a trabecular pattern and have columnar to square shapes [hematoxylin and eosin (HE) 10 $\times$]. (b) HCC has abundant granular cytoplasm with vesicular nuclei and prominent nucleoli (HE, 4000 $\times$). (c) Area of capsular invasion (HE, 40 $\times$). (d) Area containing bizarre giant cells with hyperchromatic irregular nuclei (HE, 40 $\times$). (e) The tumor shows a follicular pattern with scanty colloid and bizarre cells dispersed among the other cells (HE, 400 $\times$). (f) Solid area composed of polygonal large cells with abundant cytoplasm and pleomorphic nuclei (HE, 400 $\times$).

Histologic examination showed large tumor cells in a trabecular arrangement, small follicles with scanty colloid, and a solid pattern. The cells were polygonal to square shaped, had distinct cell borders, rounded nuclei, coarse chromatin, some vesicles with prominent nucleoli, and abundant granular eosinophilic cytoplasm (Figure 7). One section shows an area containing bizarre giant cells with irregular hyperchromatic nuclei and prominent nucleoli (Figure 8). Another area shows tumor cells with eosinophilic cytoplasm and heights three times their width (Figure 9). The tumor was diagnosed as a mixed tall cell variant of papillary thyroid carcinoma (TCVPTC) and HCC transformed to ATC. Tissue sampling from the left lobe shows adenomatous struma. Non-sentinel nodes were considered to indicate non-specific chronic lymphadenitis. Second opinions and further investigation proved that the correct

diagnosis was HCC with bizarre nuclei. ATC is difficult to manage, its management often need combination of surgery, radiotherapy and chemotherapy [2]. HCC is radio-iodine resistant and the best therapy approach has emerge controversy between expert. Some expert recommend conservative management while others suggest aggressive treatment [3].

DISCUSSION

FNAB is regarded worldwide as the first approach to thyroid nodule evaluation. It is a simple, safe, and cost-effective method for correctly characterizing the nature of a lesion in >70% cases [11, 12]. In our case, the smears showed dispersed and clustered monotonous proliferation of Hürthle cells and scanty colloid without nuclear features of papillary thyroid carcinoma. The observed features matched the diagnostic criteria for a follicular neoplasm of Hürthle cell type. In general, it is recommended that all patients with cytologically suspicious HCT undergo surgical resection [13-15].

Our patient initially underwent isthmolobectomy. Frozen section examination revealed WDTC transformed to ATC, so the surgeon decided to perform a total thyroidectomy on this patient. The mainstay of treatment for all differentiated thyroid cancers is surgical resection, and HCC is no exception. Once an HCC is histologically confirmed following diagnostic thyroid lobectomy, a complete thyroidectomy should be considered. Histopathological analysis remains the gold standard for diagnosis, although it may be apparent preoperatively if there is evidence of metastasis. Malignant HCT requires aggressive surgery because it is poorly responsive to chemotherapy, does not concentrate iodine, and is generally not radiosensitive.

Figure 7. Hürthle cells showing polygonal to square shapes with distinct cell borders, rounded nuclei, coarse chromatin, vesicles with prominent nucleoli, and abundant granular eosinophilic cytoplasm (HE, 400×).

Indeed, because of the relatively reduced avidity of HCC for radioactive iodine, and the resultant compromised efficacy of treatment, complete surgical resection is important [5, 12]. ATC is uncommonly identified as a small incidental finding after surgical resection of a predominantly non-anaplastic tumor. The role for total thyroidectomy when an initial

lobectomy has been performed is based more on the characteristics of non-anaplastic malignancy than on the incidental finding of ATC [16].

Figure 8. HCT may contain bizarre giant nuclei. This is not an indicator of malignancy, however (HE, 400 $\times$).

Figure 9. HCT arranged in a trabecular pattern. The cells are tall or columnar. Note the hyperchromatic nuclei. There are no nuclear features of papillary thyroid carcinoma (HE, 100 $\times$).

A paraffin block histopathology examination led to a diagnosis of mixed HCC and TCVPTC transformed to ATC. Further examination of the resected thyroid mass showed thyroid tissue containing a malignant tumor mass in a small follicular with scanty colloid trabecular arrangement and some solid areas. The neoplastic cells were mostly polygonal to square in shape, with distinct borders and abundant eosinophilic granular cytoplasm. Some cells were columnar with hyperchromatic nuclei. Nuclear grooves, nuclear clearing, nuclear crowding, and pseudoinclusion were not present. This finding excluded a diagnosis of TCVPTC.

Figure 10. Discohesive growth of neoplastic cells can simulate papillary structure. This is not true papillary growth (HE, 400 $\times$).

Hürthle cells are large polygonal cells with distinct borders derived from thyroid follicular epithelium. They contain abundant granular cytoplasm, because of excess mitochondria, and have a large nucleus with a prominent nucleolus. Hürthle cells can be observed in both benign and malignant conditions. The mechanism behind mitochondrial abundance in these conditions is not completely understood, but it is probably a reflection of excessive mitochondrial proliferation and/or decreased mitochondrial degradation [5, 17]. This is a phenomenon of metaplasia that occurs in inflammatory disorders, such as thyroiditis, or other situations that result in cellular stress. Oncocytes proliferation gives rise to hyperplastic and neoplastic nodules [7].

The genetic abnormalities identified in HCT include aneuploidy, H-RAS mutations, allelic alterations, and alterations in mitochondrial DNA [14]. HCT have lower prevalences of RAS gene mutation and PAX8/PPARG rearrangement than those of their counterparts lacking oncocyctic change. The TP53 mutation has been identified in 10%-20% of oncocyctic follicular carcinomas lacking high-grade or poorly differentiated features, sometimes in association with PTEN mutations [17, 18].

HCC is currently classified as a variant of follicular carcinoma and is also known as oncocyctic or oxyphilic carcinoma, which is defined as a thyroid malignancy consisting of $\geq 75\%$ Hürthle cells. HCC differs from its benign counterpart by the presence of capsular and/or vascular invasion or the presence of metastatic disease [3, 8, 17]. The histologic distinction between HCA and HCC is determined by the presence or absence of capsular and/or vascular invasion [5-19]. HCA can be distinguished from HCC with criteria similar to those for non-Hürthle follicular tumors. HCA is an encapsulated tumor, and no invasion is seen. HCT with capsular invasion is classified as minimally invasive HCC. HCT with limited vascular invasion (<4 vessels) and extensive vascular invasion (>4 vessels) is classified as an encapsulated angioinvasion HCC. Widely invasive HCC shows extensive invasion of the thyroid and extra-thyroidal soft tissue [20]. In our case, we found several foci of capsular invasion and one focal of vascular invasion. Therefore, we categorized our case as an encapsulated, angioinvasive HCC.

Figure 11. (a-c) Capsular invasion of the tumor. (d) Vascular invasion (a-d, HE, 100×).

HCC prognosis is related to the extent of vascular invasion. The more veins are invaded by tumors, the less favorable the prognosis. Factors other than vascular invasion are associated with overall survival in HCC patients. Goffredo et al. [17] determined that older age, larger tumor size, extrathyroidal tumor extension, and not undergoing surgery were associated with reduced overall survival of HCC. Tumor size is an important feature of biological behavior. A Hürthle cell tumor that is ≥ 3.5 cm has a 67% risk of malignancy [20].

Figure 12. Another feature of HCC. (a) HCC can show hemorrhagic areas. These areas can develop spontaneously or be an effect of previous FNAB (HE, 100×). (b) Solid area with voluminous eosinophilic cytoplasm, vesicular nuclei with prominent nucleoli (HE, 400×). (c, d) Predominantly solid with scattered bizarre nuclei (HE, 10×, HE, 40×).

There are some additional morphological and architectural features that can reliably differentiate benign from malignant HCT. The more accurate parameters for a carcinoma diagnosis include the concept of small-cell dysplasia, large-cell dysplasia, syncytia, crowding, and a dispersive cellular pattern [20]. The presence of mitosis, a solid or trabecular growth pattern, extrathyroidal extension, and presence of lymph node metastases are among the histologic features that predict recurrence [17].

In some neoplasm areas, bizarre giant cells are seen. The cells show large, irregular, bizarre, markedly atypical, hyperchromatic nuclei, and some vesicular with prominent nucleoli. The number of cytoplasm ranged from high to abundant, with eosinophilic and granular characteristics. These findings were previously interpreted as characteristic of the giant cell type of ATC. A second opinion pointed out that giant cells are seen in HCC. According to the literature, both benign and malignant thyroid lesions contain so-called “cells of endocrine atypia” or cells with “bizarre nuclei”, these manifest as single cells or small groups displaying marked cellular and nuclear enlargement, some degree of pleomorphism, marked cellular hyperchromasia, and occasionally macronucleoli randomly dispersed among otherwise differentiated thyroid follicular cells. Their occurrence can be extremely worrisome. When these enormous cells are observed in HCT, it is probably better not to definitively diagnose such a case as ATC [10].

We performed some immunohistochemical analyses to support our diagnosis as HCC rather than ATC. HCC will show reactivity to TTF-1 and thyroglobulin, whereas ATC will not react to either marker [10, 21]. In our case, the TTF-1 and thyroglobulin were positive in all areas, including the solid area and the area containing bizarre giant cells.

A small portion of HCC undergoes transformation to ATC [20]. HCC have a greater propensity for malignant transformation to anaplastic carcinomas than do other WDTC [7]. In our case, the immunohistochemical analyses failed to show the ATC transformation since a thyroglobulin marker showed reactivity in all tumor areas. Overdiagnosis of HCC to ATC can cause unnecessary alarm because ATC has short-term survival, with a mortality rate >90% and a mean survival time of six months after diagnosis, whereas HCC has higher survival rates ranging from 85% for minimally invasive lesions to near 10% for widely invasive cases [20].

Figure 13. The tumor showed reactivity to thyroglobulin marker (IHC 400×).

CONCLUSION

Hürthle cell proliferation can lead to hyperplastic or neoplastic nodules. HCT is a rare thyroid neoplasm of follicular cell origin, and >75% of these neoplasms are composed of cells with oncocytic features. The diagnoses of HCA and HCC are differentiated based on capsular or vascular invasion and the presence of metastases. HCC's histologic appearance is highly variable. An accurate HCC diagnosis, accompanied by identification of prognostic factors, enables evidence-based management decisions. Bizarre nuclei can occur in benign and malignant HCTs and should be assessed carefully to prevent overdiagnosis.

Chapter 347

INVASIVE BREAST CARCINOMA MIMICKING SECRETORY CARCINOMA: A CASE REPORT

***Patricia Fransisca Julianty, Primariadewi Rustamadji*
and Hartono Tjahjadi***

Department of Anatomical Pathology, Faculty of Medicine,
Universitas Indonesia, Jakarta, Indonesia

ABSTRACT

Secretory carcinoma is an exceptionally rare type of invasive breast cancer in the special subtype classification of World Health Organization 2012. It occurs in <0.15% of all breast cancers and has a distinct histomorphology, which is characterized by the presence of intracellular and extracellular eosinophilic secretory materials. It generally shows triple negativity for estrogen receptor, progesterone receptor, and human epidermal growth factor 2 and shows strong reactivity for S-100 protein. We report the case of a 54-year-old woman with invasive breast carcinoma. The histomorphology mimicked that of secretory carcinoma, with unusual immunohistochemical findings typical of secretory carcinoma. However, secretory carcinoma is associated with a characteristic translocation that creates *ETV6-NTRK3* gene fusion, which was not observed in this case. Despite the considerable resemblance with secretory carcinoma, this case was ultimately diagnosed as invasive breast carcinoma of no special type.

Keywords: invasive breast carcinoma, no special type, secretory carcinoma

INTRODUCTION

Invasive breast carcinoma is the most common carcinoma occurring in women and accounts for 23% of all cancers in women globally and 27% in affluent countries. The World Health Organization (WHO) Classification of Tumours of the Breast, Fourth Edition[1],

* Corresponding Author's Email: primariadewi@yahoo.com.

categorizes breast cancers that do not have sufficient characteristics as a specific histological type known as “carcinoma of no special type” (NST). Invasive NST carcinoma is the most common type of invasive carcinoma of the breast, accounting for 40%–75% of cases in published series [1].

Secretory carcinoma (SC) is an exceptionally rare type of breast cancer in the special subtype classification of WHO. It occurs in < 0.15% of all breast cancers [2]. It was first observed in young children and was therefore initially called juvenile breast; later, it was observed to occur in all ages and so Tavassoli and Norris recommended the term SC as a better description of its clinical spectrum and behavior [3]. SC occurs in both females and males of ages 9–69 (median, 25) years. Moreover, it can occur in any part of the breast, with the central region being the most frequent location [4]. SC has a distinct histomorphology, which is characterized by the presence of intracellular and extracellular eosinophilic secretory materials with papillary, solid, microcystic, and tubular architecture. A consistent finding is the presence of intracellular and extracellular secretory materials that is positive for periodic acid–Schiff (PAS) staining, resistant to PAS–diastase, and positive for Alcian blue (AB) staining [2, 3]. Moreover, the cells are of low to moderate nuclear grade and exhibit low mitotic activity [2–4]. SC generally shows triple negativity for estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor 2 (HER2), and strong reactivity for S-100 protein [4, 5]. It is associated with a characteristic translocation, t(12;15), which creates the *ETV6–NTRK3* gene fusion [2].

Invasive carcinoma NST has prognostic characteristics and management are similar or slightly worse compared to breast cancer as a whole. The prognosis is greatly influenced by classical variables such as histological grade, tumor size, lymph node status, vascular invasion, and the predictors of therapeutic response [1]. The prognosis for SC is better than invasive carcinoma NST: recurrence and distant metastasis are extremely rare [4], and even lymph node metastasis is associated with excellent prognosis if only a few lymph nodes are involved [6]. The management of invasive NST carcinoma depends on the prognostic and predictive characteristics [1]. There are no consensus guidelines for the treatment of SC because of its rarity, but modified radical mastectomy can be an option for tumors larger than 2 cm in diameter with poor gross circumscription [6, 7].

Here, we report a case of a 54-year-old woman with invasive breast carcinoma that mimicked SC; however, it was ultimately found not to have the fusion gene specific to SC. The histomorphology features were deceptive, and little is known about SC and its mimicking; it is therefore useful to report such cases as maximum information can be made available for precise diagnosis.

CASE REPORT

A 54-year-old woman presented with a painless lump in her right breast, which she had first noticed two years previously. It had gradually increased in size during the previous year and, 7 months previously, the patient also noticed a mass in the axillary region. There was no history of breast carcinoma in her family. She attended our hospital on September 19th 2016. A physical examination revealed a mobile, hard, firm, painless nodule with a well-defined border, located in the upper medial quadrant of her right breast in the areolar region. There

was no skin ulceration or nipple discharge. Ultrasonography showed a heterogenous hypoechoic mass with calcification in the upper inner quadrant of the right breast; it measured 2×2×2.4cm, with an ill-defined margin. In addition, there was enlargement of the right axillary lymph node without a central hilum, measuring 1.5×0.8cm. Abdominal ultrasonography and thoracic X-ray imaging showed no signs of metastatic lesions.

A core needle biopsy was performed on September 29th. The specimen showed epithelial neoplastic cells arranged in a trabecular infiltrative nest with no tubule formation. The nuclei were moderate in size and hyperchromatic, with eosinophilic cytoplasm (Figure 1). The mitotic count was fewer than 5 per 10 high-power fields. No vascular invasion was observed. The tumor was diagnosed as invasive NST carcinoma, grade 2 (tubule score = 3; nuclear score = 2; mitotic score = 1; total score = 6).

A fine needle aspiration biopsy was performed on November 21st as part of a special educational and experimental study. This revealed the tumor cells to be clustered and dispersed, with pleomorphic nuclei, coarse chromatin, and irregular membranes, with eosinophilic cytoplasm and intracytoplasmic vacuolization (Figure 2). The diagnosis was breast carcinoma.

Figure 1. Core biopsy. (a, b) The tumor cells were arranged in a trabecular infiltrative nest. (a) H&E stain, 40×. (b) H&E stain, 100×. (c, d) The nuclei were moderate in size and hyperchromatic with eosinophilic cytoplasm. Both H&E stain, 400×. H&E, hematoxylin and eosin.

A modified radical mastectomy was performed on December 7th and the specimen was sent for pathological examination. On gross examination, the tumor was 3×2.5×2.5cm in size, ill-defined, firm, and white to tan (Figure 3). It was located 2 cm from the areola in the upper inner quadrant.

Figure 2. Fine needle aspiration biopsy smears. (a) The tumor cells were clustered. Giemsa stain, 100 $\times$. (b, c) The tumor cells had pleomorphic nuclei with eosinophilic cytoplasm and intracytoplasmic vacuolization. Giemsa stain, 400 $\times$. (d) Clusters of tumor cells. Papanicolaou stain, 400 $\times$.

Figure 3. Gross specimen. The tumor was firm and ill-defined.

Microscopic examination showed the tumor mass had a solid pattern with infiltrative nests. Tubule formation was observed in less than 10% of the tumor area. The tumor cells had round or oval nuclei that varied in size from moderate to large. They were vesicular, with scattered nucleoli and eosinophilic to pale cytoplasm. The cytoplasm was vacuolated, with abundant eosinophilic material in the lumina (Figure 4). The mitotic count was 6 per 10 high-power fields. There was no tumor infiltration into the areola, skin, or surgical margins. When

the secretory material was stained with PAS and AB, the PAS staining persisted after diastase digestion (Figure 5). Specimens from dissection of the axillary lymph nodes at levels I and II revealed metastasis in one of the three lymph node. On the basis of these findings, the tumor was diagnosed as SC, grade 2 (tubule score = 3; nuclear score = 3; mitotic score = 1; total score = 7), with a recommendation for immunostaining.

Figure 4. (a, b) Tumor cells showing the solid pattern and infiltrative nest. (a) H&E stain, 40 $\times$. (b) H&E stain, 100 $\times$. (c, d) The tumor cells had round or oval, moderate to large nuclei, which were vesicular, with scattered nucleoli and eosinophilic to pale cytoplasm. The cytoplasm was vacuolated with eosinophilic material. H&E stain, 400 $\times$. H&E, hematoxylin and eosin.

Figure 5. The eosinophilic material. The specimen was (A) positive for periodic acid-Schiff (PAS) staining, (B) resistant to PAS-diastase, (C) and positive for Alcian blue staining. All 400 $\times$.

Immunohistochemically, the neoplastic cells were positive for ER (80%), negative for PR, and expressed HER2 with a score of 2+ (weak membranous staining). Subsequent chromogenic in situ hybridization showed no amplification of HER2. In addition, 15% of the tumor cells were positive for Ki67, and the cells were negative for S-100 protein, positive for carcinoembryonic antigen, positive for E-cadherin, and negative for CD117 (Figure 6).

Figure 6. Immunohistochemical staining showed that the cells were (a) estrogen receptor-positive, (b) progesterone receptor-negative, (c) did not overexpress HER2, (d) positive for Ki67 (15% of the cells), (e) negative for S-100 protein, (f) positive for E-cadherin, (g) positive for carcinoembryonic antigen, (h) and negative for CD117. All 400 $\times$.

Figure 7. Results of the *ETV6*–*NTRK3* fusion gene test using a fluorescence in situ hybridization break-apart probe. (a, b) The cells were negative for the *ETV6* translocation. (c, d) The cells were negative for the *NTRK3* translocation.

Aparaffin-embedded cell block was tested for the *ETV6*–*NTRK3* fusion gene, which characterizes SC, at the Prince of Wales Hospital, Hong Kong, using a fluorescence in situ hybridization break-apart probe kit. This demonstrated the absence of the *ETV6*–*NTRK3* fusion gene (Figure 7).

The patient was administered aromatase inhibitor hormonal therapy, anastrozole, without chemotherapy or radiotherapy. At 10 months after the surgery, she remains well, without local recurrence or distant metastases.

DISCUSSION

SC is a rare subtype of breast malignancy that accounts for less than 0.15% of all breast cancer [2]. During a six-year period, from January 2011 until December 2016, our hospital experienced only three cases, although none of these were tested for the fusion gene.

The signs and symptoms of our patient initially appeared to be consistent with SC. She was aged 54years; SC has been at ages from 9 to 69 [3], with about one-half of cases older than 20 years, and a substantial number aged between 50 and 69 years [8]. The nodule in her right breast was painless and was first noticed two years two years previously, gradually increasing in size over the previous year. SC is a slow-growing, painless, well-circumscribed,

mobile, palpable mass [2,6]. In our patient, the single mass was 3×2.5×2.5 cm in size, ill-defined, firm, and white to tan in color, and it was located 2 cm from the areola in the upper inner quadrant. SC can occur in any part of the breast, with the central region of the breast the most prevalent location. It usually grows as a single mass and ranges in size from 0.5 to 12 cm (mean, 3 cm) [2, 8]. The cut surface varies from grayish-white or yellow to tan in color [2, 3].

Fine needle aspiration smears of SC are characterized by the presence of a globular structure comprising small, centrally located, mucoid material, usually covered by two or three, or occasionally more, epithelial cells. The presence of grape-like clusters of vacuolated cells can be another helpful cytologic feature. Other findings of SC include prominent intracytoplasmic vacuolization and occasional signet ring cells. Some cells contain granular cytoplasm. The nuclei are crescent-shaped or ovoid, with moderate to low nuclear-to-cytoplasmic ratios. Most of the cells have a bland appearance, although some can appear alignant [8-12]. In our case, the fine needle aspiration smears revealed tumor cells that were clustered and dispersed. It showed a frankly malignant appearance, with pleomorphic nuclei, coarse chromatin, and irregular cell membranes, with eosinophilic cytoplasm and prominent intracytoplasmic vacuolization. Some parts of the smears contained structures that mimicked the globular structures and grape-like clusters that are the most characteristic features of SC [8]. However, although we observed globular structures and prominent intracytoplasmic vacuolization, the tumor cells showed a frankly malignant appearance, which is unusual for SC.

The core biopsy specimen showed the same histological features as the mastectomy specimen. Microscopically, SC is usually circumscribed, although it sometimes exhibits overtly infiltrative growth. It is arranged in papillary, microcystic, ductal, and solid patterns [2, 8]. Our case showed an infiltrative tumor arranged in a solid nest.

SC tumor cells can have secretory or apocrine features. The cytoplasm of the SC cells of a secretory nature is pale to clear, pink or amphophilic, and contains abundant secretions. The nuclei appear to be low-grade and are small to moderate in size, and those with pale chromatin usually contain small uniform nucleoli. The chromatin ranges from dark and finely dispersed to pale and granular. Cells with apocrine features contain granular eosinophilic cytoplasm and the nuclei are characteristic of those of apocrine cells. It is usual to observe both secretory and apocrine types of cell in a carcinoma, although one type can predominate [8]. In our case, the tumor cells had round or oval nuclei that were moderate to large in size, vesicular and with scattered nucleoli. In SC, the tumor cells typically have a blander appearance, with nuclei that are small to moderate in size and less pleomorphic, but SC with intermediate or high nuclear atypia has been reported [13]. SC is usually associated with low mitotic activity [2, 4, 6]. The mitotic activity of our case was as low as that found in SC.

The presence of intracellular and extracellular secretory material that is PAS-positive, PAS-diastase resistant, and AB-positive is a consistent finding in SC [2]. The secretion accumulates within the tumor cells, in glands formed by the tumor cells, and in the microcystic spaces associated with the tumor cells. With hematoxylin and eosin staining, the secretory material appears pale pink or amphophilic, and it often contains lacunae that give the appearance of bubbles [8]. In our case, the vacuolated cytoplasm with abundant eosinophilic material that was PAS-positive, PAS-diastase resistant, and AB-positive led us to diagnose it as a special type of breast carcinoma.

On immunostaining, SC generally shows as triple negative for ER, PR, and HER2, with strong reactivity for S-100 [5]. Our case was ER-positive, but PR-negative and HER2-negative. Although there have been some reported cases of SC that were positive for ER, this is unusual [14-16]. Our case was negative for S-100 protein. We were unable to find any previous reports of S-100 protein-negative SC, so this finding did not support the SC diagnosis.

In SC, Ki67 levels vary from less than 1% to 34%, and E-cadherin is positive [8]. In our case, Ki67 was positive in 15% of the nuclear tumor cells and E-cadherin was positive. Positivity or negativity for the carcinoembryonic antigen varies in SC, whereas CD117 is positive in 70% of cases [4, 8]. Our case was positive for the carcinoembryonic antigen and negative for CD117.

The differential diagnosis included acinic cell carcinoma, cystic hypersecretory carcinoma, carcinoma with apocrine differentiation, cribriform carcinoma, glycogen-rich carcinoma, and lipid-rich carcinoma, as well as invasive NST carcinoma [4, 6, 17]. Acinic cell carcinomas, which are even less common than SC, present with cells containing basophilic granules. They can closely resemble SC; as with SC, they are triple negative for ER, PR, and HER2 and usually positive for S-100 protein [4]. Osako *et al.* proposed four markers for distinguishing between SC, acinic cell carcinoma, cystic hypersecretory carcinoma, and common invasive breast carcinoma: *ETV6* rearrangement, amylase, α -lactalbumin, and adipophilin [17]. Cystic hypersecretory carcinomas comprise grossly evident cystic spaces filled with densely eosinophilic secretory material, with scant cytoplasm [4]. Carcinomas with apocrine differentiation are invasive, with all or nearly all of the tumor cells exhibiting apocrine cytologic features, and no intracellular vacuoles. They are usually negative for ER and PR and positive for androgen receptors [6]. Cribriform carcinomas typically have less cytoplasm and lack the foamy eosinophilic quality. There is often secretion, but this is not darkly eosinophilic, and they are usually positive for ER and PR and negative for HER2 [4]. Glycogen-rich carcinomas show PAS-positivity and are sensitive to diastase digestion, whereas lipid-rich carcinomas show abundant microvacuolated, foamy, or clear cytoplasm due to lipids that are not stained by PAS or AB [6].

Fusion of the *ETV6* and *NTRK3* genes results in a chimeric tyrosine kinase protein that displays potent transforming activity for fibroblast and mammary ductal epithelial cells. It is characteristic of SC, detected using fluorescence in situ hybridization [2, 8, 18-20]. The absence of the *ETV6-NTRK3* fusion gene in our case confirmed that the diagnosis was not SC, despite all its morphological resemblance with SC. Because there were insufficient characteristics to achieve a specific histological type classification, the case was ultimately classified as invasive NST carcinoma.

The prognosis for invasive NST carcinoma is influenced profoundly by the classical variables of histological grade, tumor size, lymph node status, and vascular invasion and by predictors of the therapeutic response. Invasive NST carcinoma and other invasive breast carcinomas are routinely graded based on an assessment of tubule/gland formation, nuclear pleomorphism, and mitotic count. Grade is a powerful prognostic factor [1]. According to the Elston–Ellis system, our case was grade 2 (moderately differentiated). Invasive carcinomas are divided into four subtypes based on protein expression patterns: luminal A, luminal B, HER2-enriched, and basal [1]. The subtype of our case was luminal A, which has a favorable prognosis.

It is important to differentiate between SC and invasive NST carcinoma because they differ in their prognosis [8, 17]. The prognosis is more favorable for SC: even patients with lymph node metastasis have an excellent prognosis if only a few lymph nodes are involved [6, 21], and recurrence and distant metastases are extremely rare [4].

Invasive NST carcinoma should be managed according to its prognostic and predictive characteristics. Most cases benefit from hormonal treatment, but the benefit of chemotherapy less clear [1]. Because of its rarity, there are no consensus guidelines for the treatment of SC. A recent report describes the successful treatment of a patient with SC with targeted therapy, the tyrosine kinase inhibitor larotrectinib [22]. In our case, after the modified radical mastectomy and axillary lymph node dissection, the patient was given anastrozole, an aromatase inhibitor, and hormonal therapy.

SUMMARY

SC is a rare breast malignancy, which consistently shows the presence of intracellular and extracellular secretory material that is PAS-positive, PAS-diastase resistant, and AB-positive, and is usually triple negative for ER, PR, and HER2, with strong reactivity for S-100 protein. It is associated with a characteristic translocation that creates *ETV6–NTRK3* gene fusion. The present case showed histomorphology that mimicked SC, with prominent eosinophilic secretory material that stained positive for PAS, PAS-diastase, and AB; however, the nuclear features were more pleomorphic than is typical of SC, and immunostaining showed features unusual for SC (ER-positive and S-100 negative). Cases with histomorphology features of SC but has unusual immunohistochemical findings typical of SC must be tested for the *ETV6–NTRK3* fusion gene prior diagnosed as SC. Despite the resemblance to SC in this case, the absence of the *ETV6–NTRK3* fusion gene excluded SC as a diagnosis and this case was ultimately diagnosed as invasive NST carcinoma.

ACKNOWLEDGMENTS

I would like to thank Gary Tse for helping us with fusion gene examination and his guide, Dr. Diahrini SpPA(K), for support during the process of writing this report. I also would like to thank fellow residents and my beloved friends for their assistance and support.

ABSTRACT

Langerhans cell histiocytosis (LCH) is a rare clonal proliferative disorder of Langerhans cells with unknown etiology, which occurs predominantly in male children. Histopathology features show polymorphous cells arranged in diffuse sheets. This case study involved the case of a patient who exhibited a nodular pattern that was unusual for LCH. The aim of this case report is to share experience about the unusual histology of LCH. An eleven-month-old boy presented with enlarged neck and inguinal lymph nodes. Ultrasound showed multiple enlargements of the lymph nodes with hypervascularization and a regular and distinct border. The patient underwent open surgical biopsy and the specimen was sent for histopathology analysis. The histopathology showed a nodular pattern with the characteristics of Langerhans cells that have abundant eosinophilic cytoplasm and the presence of nuclear grooves, nuclear folding, and inflammatory cells. The immunostaining was positive for CD1a, Langerin, S100, and CD68. In most cases of LCH, the morphology features showed polymorphous cells arranged in diffuse sheets. There are to our knowledge no published reports to date that show LCH in the nodular pattern. Whether or not there is different pathogenesis or biological behavior in nodular LCH remains unclear.

Keywords: histopathology, immunostaining, langerhans cell histiocytosis

INTRODUCTION

Langerhans cell histiocytosis (LCH) is a rare disease that involves the clonal proliferation of cells with dendritic cell features that can affect many organs. The lesion consists of LCH cells that resemble epidermal antigen-presenting dendritic Langerhans cells [1,2]. LCH was named after the founder Paul Langerhans in 1868, and the Langerhans cell is mononuclear cell, approximately 10 to 15 μm in diameter and contains the Birbeck granules [3].

Patients with LCH can be of any age, but it occurs most commonly in children, with a greater occurrence in males (ratio ranging from 1.2:1 to over 2:1) [3,4,5].

Many names have been used previously to refer to LCH, including histiocytosis X, eosinophilic granuloma, Letterer Siwe disease, and Hand Schüller Christian disease. To date the etiology of LCH is unknown, and there is a lack of understanding regarding the pathogenesis of LCH. The clinical presentation of LCH also varies from isolated single system disease to a life-threatening multisystem condition. Patients may have systemic symptoms like fever, pancytopenia, skin manifestations, widespread bone lesions, lymphadenopathy, and hepatosplenomegaly [1,4-7].

LCH is classified as either a single system or multi system disease whereby the single system disease is when the disease affects only one organ, and the multi system affects two or more organs [7]. Lymph node involvement can be part of a widespread disease that also involves other organ systems. However, LCH can also be localized to one region.

Histology and immunostaining are used to diagnose LCH. Histopathology reveals polymorphous cells arranged in diffuse sheets. There are no reports that show cells arranged in a nodular pattern. The nuclear characteristics are irregular with prominent folds, grooves, fine chromatin, inconspicuous nucleoli, and having moderately abundant eosinophilic cytoplasm. Patients with LCH typically present with a background of inflammatory cells like eosinophils, neutrophils, macrophages, and lymphocytes and the mitotic activity varies in number. LCH is characterized by the expression of CD1a, S100, and Langerin [3,4,8,9]. In 1987, the Histiocyte Society Writing group defined the criteria for the diagnosis of LCH by the presence of Birbeck granules visible via electron microscopy or by positive CD1a immunostaining. Presence of positive CD1a and Birbeck granules in the lesion is the current gold standard for the diagnosis of LCH [5,6,10].

Treatment decisions depend on whether there is a low or high risk of organ involvement and the extent of the disease at the time of diagnosis. Treatment options may include surgery, chemotherapy, radiation, and corticosteroid therapies. Patient prognosis depends on age, the extent of organ involvement, and response to initial treatment [4]. In this research study, we report the clinical and pathologic features of an eleven-month-old boy with LCH and nodular morphologic features.

CASE REPORT

An 11-month-old boy with multiple lumps on his neck for 10–12 days came to a private hospital on 5th December 2014. He underwent a neck ultrasound and chest X-ray on 6th December 2014, and the ultrasound examination showed multiple enlargements of the lymph nodes with hypervascularization and a regular and distinct border. The size of the largest

lymph node was 1.42×1.35 cm on the right side of the neck and 1.62×0.97 cm on the left side of the neck. The thyroid was normal. Lymphadenopathy was concluded from the ultrasound.

The chest X-ray showed the widening of the superior mediastinum with normal heart and hilum, and therefore interstitial pneumonia was concluded.

On the 19th of December 2014, the patient came to the Cipto Mangunkusumo Hospital complaining of a high fever that had persisted for one month. The other complaints were productive cough for one week and multiple lumps on the left and right side of his neck which initially looked like a bean and became bigger within the final two weeks. There was no weight loss, no history of going pale, bleeding, or of abdominal enlargement. There was also no family history of these symptoms. On physical examination, the patient was conscious, had no fever, was 76 cm tall, and weighed 9.1 kg. There were enlarged lymph nodes on the neck and submandible, with the largest size being 1.5×2 cm. The nodules were not tender but rather were firm in consistency and fixed to the surrounding tissue. These nodules were also accompanied by an enlarged inguinal lymph node approximately 0.5 cm in diameter.

On pulmonary examination, there were no rales or wheezing. The patient was then diagnosed with bilateral neck lymphadenopathy, and a biopsy was ordered.

On the 20th December 2014, the patient was referred to the pediatric hematology division, and it was suspected that he had a malignancy because there was no response to the antibiotic. Therefore, the next plan for this patient was to wait for the results of the biopsy. The blood test results from the 20th of December 2014 showed a hemoglobin concentration of 9.2 g/dl, 29.7% hematocrit, leukocyte 8920/uL, thrombocyte 614.000/uL, ureum 22 mg/dl, and creatinin 0.20 mg/dl. On the 22nd of December 2014, the laboratory test for LDH was 573 U/L, and on the 24th of December the patient underwent abdominal and neck ultrasound. The result of the abdominal ultrasound was normal while the neck ultrasound showed lymphadenopathy colli with suspected malignancy.

The biopsy was done on the 23rd December 2014, and the histopathology features showed some lymph nodes with the capsule consisting of a tumor mass that had a diffuse pattern and some tumor masses with a nodular pattern that was separated by connective tissue. The tumor cells had round/oval nuclei, some with a nuclear groove, and fine chromatin with abundant eosinophilic cytoplasm.

There were also multinucleated histiocytes. Mitosis was $<10/10$ HPF. Eosinophils, lymphocytes, and neutrophils were also present. Based on these features we concluded that the patient had Langerhans cell histiocytosis and therefore recommended immunostaining analysis (Figure 1-4).

We also performed immunostaining to support the diagnosis. The immunostaining was positive for CD1a, S100 protein, Langerin (performed by Prof TSY, SGH), and CD68, and negative for LCA, BCL6, CD10 (Figure 5, 6). The immunostaining confirmed the diagnosis of Langerhans cell histiocytosis and the patient received chemotherapy and was given Vinblastin, Etoposide, 6-MP, and Prednisone. At the time of study, the patient was still under control and showing recent signs of improvement.

DISCUSSION

LCH is characterized by the proliferation of pathologic cells with the phenotype of Langerhans cells (LCs) [5]. The Langerhans cell is a dendritic cell or antigen that originates from bone marrow and migrates through the blood to regional lymph nodes via the afferent lymphatics. Silberberg-Sinakin et al. in their study demonstrated the migration of Langerhans cell with an attached antigen to the afferent lymphatics and their appearance in the paracortical zone of regional lymph nodes, where they could present antigen to T-lymphocytes. This process is mediated by a local cytokine response. In regional lymph nodes, LCs interact with antigen-specific T-cells that are activated and proliferate to form effector and memory T-cells. LCH cells are derived from mature LCs that have been transformed. Yu et al. in their study demonstrated that LCH cells have little or no alloantigen presenting capacity because of suppressor cytokines that inhibit the function of the LCH cell. LCH cells will produce a wide variety of cytokines. The cytokines include IL-2, IL-3, IL-4, IL-5, IL-7, TNF- α , IL-1 α , GM-CSF, IFN- γ and cause decreased apoptosis resulting in the accumulation of LCH cells. Circulating cytokines may be responsible for organ damage and responsible for systemic disease symptoms particularly fever, which may be related to the production of IL-1 β and failure to thrive, which may be due to TNF- α production. Little is known about the molecules involved or about the routes taken by homing cells to find their way into the lymph nodes. Chemokines such as CCR1, CCR2, CCR5, CCR6, and CXCR1 are also important for the migration of LCs [5].

The etiology and pathogenesis of LCH are still unclear and whether this is a reactive process or a neoplasm has long been debated. Evidence of clonality in LCH was reported to support LCH as a neoplastic process [1,11]. A mutation of the BRAF proto-oncogene typically occurs in 38%–69% of LCH patients and supports the neoplastic origin. The BRAF mutation activates the RAS-RAF-MEK-ERK pathway that is involved in many neoplastic diseases. Activation of the BRAF gene leads to the production of a BRAF V600E mutant protein and was found in more than half of all LCH cases, suggesting that this is a genuine driver mutation in this disease [12,13].

Patients with LCH can be of any age, but it is most common in children aged one to three years old [7,14]. Males are affected more frequently with the ratio ranging from 1.2:1 to over 2:1. Singh T et al. in their study reported that the incidence of LCH is 0.5–5.4 million/year with children under 15 years old affected more than 50% [13]. There are 40 cases of LCH reported from the Anatomical Pathology Department Faculty of Medicine Cipto Mangunkusumo Hospital from 2005 until 2015. Twenty-one cases were males and 19 cases were females. In our case, the patient was an eleven-month-old boy.

Many organs can be involved in LCH including bone, lung, lymph node, skin, liver, spleen, and bone marrow. The organs have been classified into low and high-risk organs. The low-risk organs include skin, bone, lungs, and lymph nodes. The high-risk organs include liver, spleen, and bone marrow. However, a small subset of LCH patients present with isolated lymphadenopathy and with no other systemic signs or symptoms. Cervical lymph nodes are most frequently affected but supraclavicular, axillary, and inguinal lymph nodes can also be involved [7]. In our case, the patient had a single system and low-risk organ involvement that was neck and inguinal lymph nodes.

The clinical symptoms of LCH are varied and depend on the site of involvement. If affected, the lymph nodes will be enlarged. In our case, the patient had a lump on his neck and inguinal region.

The diagnosis of LCH is based on morphological and immunostaining analysis [10,14]. In our patient, the definitive diagnosis was made based on the morphological and immunostaining analysis of the lymph node biopsy specimens. In most cases of LCH, the morphology shows polymorphous cells arranged in diffuse sheets. There was no report published that showed LCH in nodular patterns. The mechanism by which LCH cells proliferate and accumulate as a nodular aggregate remains unknown. In our case, we found that cells were arranged in nodular features with Langerhans cell characteristics. This is the first case of LCH with nodular features that we have treated at the Cipto Mangunkusumo Hospital. When we first saw this pattern, we thought that it mimics follicular lymphoma. The morphological diagnosis rests on the characteristic morphology of the Langerhans cells. Langerhans cells have moderate to abundant amounts of eosinophilic cytoplasm and the presence of classical nuclear grooves and folds (“twisted towel” nuclei). The background is characteristically rich in eosinophils with varying amounts of macrophages and small lymphocytes, and neutrophils and plasma cells are absent or rare.

Multinucleated histiocytes are more numerous in bone lesions than in skin, lung, or lymph nodes. Immunostaining characteristics for LCH include positivity for CD1a, Langerin, and S100 protein. Additionally, the cells are positive for vimentin, CD68, and HLA-DR. CD45 expression is low. Ki67 is highly variable. We found the features above in the present case. The follicular lymphoma was excluded by immunostaining because it was negative for BCL6 and CD10. Electron microscopy searching for cytoplasmic granules, called Birbeck

granules, wasn't done for this patient. Birbeck granules are specific for Langerhans cell and have a tennis racket-like appearance, are 200–400 nm long and 33 nm wide, and contain the protein Langerin [3,10].

The differential diagnosis of LCH includes Langerhans cell sarcoma, Rosai–Dorfman disease, and Dermatopathic lymphadenopathy [1,9]. Langerhans cell sarcoma can be distinguished from LCH by the presence of high-grade nuclear atypia and high mitotic rate. Rosai–Dorfman disease is sinus histiocytosis with massive lymphadenopathy, and the sinuses are distended by distinctive histiocytes that have round nuclei, central nucleoli, and abundant cytoplasm with well-defined cytoplasmic membranes and common emperipolesis. Langerhans cell sarcoma is most common in children. The immunostainings are positive for the S100 protein and CD68, but negative for CD1a. Dermatopathic lymphadenopathy is composed of interdigitating dendritic cells and Langerhans cells that expand to the paracortical area of the lymph node. Dermatopathic lymphadenopathy has a nodular growth pattern, pigment-laden histiocytes, and absence of necrosis or eosinophil background [9].

Patient prognosis is based at the age of first diagnosis, on whether there is a low or high risk of organ involvement, and on responses to the initial round of therapy. Single system LCH has a good prognosis with more than 80% remaining disease-free after initial therapy. In our case, the patient was 11 months old at first diagnosis, had a single organ LCH that involved the lymph nodes, and responded well to the initial treatment [1,6].

A wide spectrum of treatment modalities has been adopted to deal with LCH, including surgical excision combined with radiotherapy. Other treatment strategies have been suggested and include chemotherapy, isolated radiotherapy, and the use of corticosteroids [15]. In the present case, the patient underwent open surgical biopsy, chemotherapy and was given corticosteroids. He has now completed chemotherapy and is due for follow-up at the clinic once every six months.

CONCLUSION

LCH is a rare disease that can impact any age group but is most commonly seen in young children. In most cases, the morphological features showed polymorphous cells that arrange in diffuse sheets, but the pathologist must be aware that there is another different feature of LCH that was nodular. This pattern mimics follicular lymphoma but was excluded by immunostaining that was negative for BCL6 and CD10. The immunostaining was positive for CD1a, Langerin, S100, and CD68. Whether or not there is different pathogenesis or biological behavior in nodular LCH remains unclear. Treatment options include surgery, radiotherapy, chemotherapy, and corticosteroids. Our patient received Vinblastin, Etoposide, 6-MP, and Prednisone and responded well to the treatments.

ABSTRACT

Rhabdomyosarcoma (RMS) is the most common soft tissue malignancy occurring in childhood and adolescence. RMS was previously classified into the following three main subtypes: embryonal, alveolar, and pleomorphic. In the latest classification, a new variant of RMS, spindle/sclerosing RMS, has been included. This variant is rare, occurring in 5%–10% of all cases of RMS. It is characterized by prominent hyaline and sclerosis stroma that mimics an osteoid or chondroid with a pseudovascular, microalveolar, or cord growth pattern. Therefore, it might be easily mistaken during initial evaluation as osteosarcoma, chondrosarcoma, angiosarcoma, infiltrating carcinoma, spindle cell sarcoma, or other RMS types. Awareness of the existence of this entity is important for not only diagnosis but also prognosis and treatment. Here we present the case of a child with sclerosing RMS that was not easily diagnosed. This report aims to discuss the potential diagnostic pitfalls associated with other look-alike sarcomas.

Keywords: rhabdomyosarcoma, sclerosing rhabdomyosarcoma

INTRODUCTION

Rhabdomyosarcoma (RMS) is the most common soft tissue malignancy in childhood and adolescence, accounting for 5%–8% of all pediatric malignancies [1, 2]. According to the World Health Organization (WHO) 2013 classification, RMS can be classified into the following four subtypes: embryonal (including botryoides and anaplastic variants), alveolar (including solid and anaplastic variants), pleomorphic, and spindle cell/sclerosing RMS [3].

The latest WHO classification has grouped spindle cell and sclerosing RMSs into a single pathological entity, as both commonly share overlapping histological features. It is considered that spindle cell and sclerosing RMSs are a continuous spectrum [1, 4]. Sclerosing RMS was first reported by Mentzel and Katenkamp in 2000, and since then, additional cases with similar features have been described [5]. This variant is rare and accounts for 5%–10% of all cases of RMS [3, 4, 6]. It occurs over a wide age range (0.3–79 years) and shows male predominance [2, 3, 7, 8]. Its symptoms might vary depending on the location and size. Although spindle cell and sclerosing RMSs are under the same pathological group, their site predilections differ. Spindle cell RMS occurs predominantly in the para-testicular region among pediatric patients and in the head and neck region and at genitourinary sites among adult patients [3, 6]. On the other hand, sclerosing RMS commonly affects the extremities and the head and neck region [2, 6].

Macroscopically, both tumors show a well-demarcated border, with a mean size >5 cm [3, 4, 6]. Additionally, the outer surface appears gray/white. In a cut section, necrosis and hemorrhage might be noted [3]. Histologically, the term spindle cell RMS is used when fascicular or intersecting spindle cell morphology is the prominent feature (>80% of the tumor area), with rare, scattered eosinophilic rhabdomyoblasts [3, 6]. Therefore, it might resemble other spindle cell sarcomas [4]. On the other hand, sclerosing RMS is characterized by abundant production of a hyaline matrix, which imitates a primitive osteoid or chondroid; thus, it might be confused with osteosarcoma or chondrosarcoma at the initial evaluation. The tumor cells are usually arranged in a pseudovascular/microalveolar pattern; thus, the tumor might be mistaken for angiosarcoma or alveolar RMS [3–6]. Most cases show mixed features of spindle and sclerosing patterns. Immunohistochemically, spindle cell RMS shows positivity for desmin (diffuse), myogenin (nuclear expression), smooth muscle actin (SMA), and muscle-specific actin (MSA). On the other hand, sclerosing RMS shows strong positivity for myoD1 [3].

Spindle cell and sclerosing RMSs have distinct genetic abnormalities that differentiate them from other RMS types. They are characterized by the presence of *NCOA2* and *VGLL2*-related fusions in congenital/infantile cases and *MYOD1* mutations co-existing with *PIK3CA* mutations in both pediatric and adult cases [1, 4]. Overall, spindle cell and sclerosing RMSs arising in adult patients have more aggressive behaviors when compared with tumors arising in pediatric patients [4].

Here, we present a child with sclerosing RMS that was not easily diagnosed. This report aims to share the potential diagnostic pitfalls associated with other look-alike sarcomas. Understanding of histopathological features and appropriate use of immunohistochemical analysis are essential to achieve an accurate diagnosis.

CASE REPORT

An 8-year-old girl had an enlarging mass in the left mandibular region since 1 year before admission to our hospital. Initially, she complained about severe toothache at her left jaw. Following tooth extraction, her gum swelled and gradually increased in size, causing difficulty in eating and drinking.

Clinical examination revealed that she was stunted and underweight (both height and weight for age were below $-3SD$). A large mass measuring $10 \times 5 \times 2.5$ cm was noted at the left buccal and mandibular region, and lymphadenopathy measuring 1 cm in diameter was noted at the right colli (Figure 1). Laboratory results indicated hypochromic microcytic anemia (hemoglobin level, 8 g/dL; mean corpuscular volume, 64 fL; mean corpuscular hemoglobin, 19 pg/ml; mean corpuscular hemoglobin concentration, 30 g/dL), leukocytosis ($14,500/\mu\text{L}$), and thrombocytosis ($690,000/\mu\text{L}$). She was clinically suspected to have RMS.

Plain radiography and computed tomography showed a multilobulated soft tissue mass extending from the deep maxillary and neck region. Tumoral expansion resulted in bony thinning and deformity of the left zygoma, maxilla, and mandible. The tumor occupied the left oral cavity. There was no significant bone destruction (Figure 2 a-c). Magnetic resonance imaging showed a solid heterogeneous mass with a necrotic component. These findings were consistent with a malignant soft tissue neoplasm (Figure 3 a-d).

Debulking excision surgery was performed, and it resulted in 70% mass reduction. The surgical specimens were sent to the Anatomical Pathology Department. There were 11 resected specimens varying in size from $3 \times 2 \times 0.5$ cm to $8 \times 6 \times 3$ cm (white to brownish in color), with firm consistency. In a cut section, a yellowish mass was noted without hemorrhage or a necrotic area (Figure 4).

Figure 1. Mass at the left buccal and mandibular region at the initial presentation.

Histopathological examination showed mesenchymal tumor cells arranged in diverse patterns, including solid, microalveolar, and linear patterns (Figure 5 a-c). Some areas showed alternating hypercellular and hypocellular zones (Figure 5 d) with a myxoid stromal

background (Figure 5 e). The tumor cells appeared round/oval and spindle shaped with marked nuclear pleomorphism and bizarre, hyperchromatic, or vesicular nuclei, and some cells showed conspicuous nucleoli and eosinophilic cytoplasm (Figure 5 f). Typical mitosis and atypical mitosis were easily found. A lace-like osteoid matrix mimicking that in osteosarcoma was seen interspersed between tumor cells (Figure 5 g). Additionally, there was prominent hyaline stroma (Figure 5 h). No rhabdomyoblasts were noted. These microscopic findings initially concluded as conventional osteosarcoma.

Figure 2. Radiography and computed tomography. (a) Plain radiography, lateral projection; (b, c) Computed tomography with three-dimensional bone reconstruction.

Figure 3. Magnetic resonance imaging. (a) T1 contrast, coronal; (b) T1 contrast, sagittal; (c) T1, axial; (d) T2, coronal.

Figure 4. Gross specimens. Firm tumors varying in size (white to brownish in color) without hemorrhage or a necrotic area.

Figure 5. Histological analysis. (a) Solid pattern (hematoxylin and eosin [H&E], magnification 100×); (b) Microalveolar pattern (H&E, 40×); (c) Linear pattern (H&E, 40×); (d) Alternating hypercellular and hypocellular zones (H&E, 40×); (e) Myxoid stromal background (H&E, 40×); (f) Tumor cells and mitosis (H&E, 400×); (g) Osteoid-mimicking matrix (H&E, 400×). (h) Prominent hyaline and sclerosis matrix (H&E, 100×).

Figure 6. Immunohistochemical analysis. (a) Desmin (cytoplasmic positive, diffuse; magnification 400×); (b) MyoD1 (nuclear strong positive, diffuse; 400×); (c) Myogenin (nuclear positive, focal; 400×); (d) SMA (cytoplasmic positive, focal; 400×).

A tumor board meeting was held owing to the discrepancy between the clinical diagnosis and histopathological results. Immunohistochemical analysis was then performed (Figure 6 a-d). The neoplastic cells were immunopositive for desmin (cytoplasmic positive, diffuse), myoD1 (nuclear strong positive, diffuse), myogenin (nuclear positive, focal), and SMA (cytoplasmic positive, focal). Thus, the diagnosis of sclerosing RMS (WHO grade 3) was confirmed.

DISCUSSION

Sclerosing RMS has been reported to occur over a wide age range, including in pediatric patients, and males are six times more frequently affected than females [2, 3, 7, 8]. The two most common sites of involvement are the extremities and head and neck region [2, 6, 9]. Lesions usually form a large bulky mass with a median size >5 cm [3, 4, 6]. Our present 8-year-old female patient had an enlarging mass measuring 10×5×2.5 cm in her left mandibular region. Our findings are similar to the findings of these previous reports in terms of onset age, predilection site, and tumor size at presentation.

Microscopic examination revealed that the tumor produced abundant hyaline stroma mimicking a primitive osteoid in conventional osteosarcoma. The tumor cells were round/spindle shaped with pleomorphic nuclear and brisk mitotic figures arranged in various patterns. The presence of solid and microalveolar patterns might resemble the appearance of alveolar RMS, alternating cellular zones with myxoid background stroma might resemble the

appearance of embryonal RMS, and a linear pattern might resemble the appearance of metastatic breast carcinoma.

Classically, conventional osteosarcoma has a bimodal age distribution (10–14 years of age and >40 years of age) with long bone predilection sites, especially the femur [3, 10]. It is composed of pleomorphic or anaplastic tumor cells in a permeative pattern with an osteoid lace-like matrix in between cells (Figure 7 a) [3, 10]. It genetically exhibits complex abnormalities [3], and there are no specific immunohistochemical studies to confirm a diagnosis of osteosarcoma [10]. The tumor in our case also showed nuclear pleomorphism with a mimicking osteoid lace-like matrix in between cells (Figure 7 b). It can be very difficult to subjectively distinguish between an osteoid and eosinophilic extracellular matrix [3]. Immunohistochemical analysis confirmed that the origin of the tumor cells was skeletal muscle.

Figure 7. Comparison between conventional osteosarcoma case and the tumor in the present case. (a) Conventional osteosarcoma with osteoid lace-like matrix (H&E, 400×) (arrow head); (b) Prominent hyaline stroma in sclerosing rhabdomyosarcoma mimicking an osteoid matrix (H&E, 400×) (arrow).

Classically, alveolar RMS arises in adolescents and young adults, with soft tissue extremities as the predilection site [3, 8, 11]. It is composed of nests containing primitive round cell tumors separated by thin fibrous septa creating a pseudoalveolar pattern (Figure 8 a) [3, 11]. The nests usually show central loss of cohesion and are peripherally arranged in a picket fence-like arrangement [3, 12]. Wreath cells with rhabdomyoblastic differentiation might also be noticeable [3]. The solid variant of alveolar RMS lacks fibrous septa and forms a tumor sheet [3]. It genetically exhibits either *PAX3-FOXO1* or *PAX7-FOXO1* fusion genes [3, 13]. Immunohistochemical analysis shows diffusely positive staining for myogenin [3, 12]. On the other hand, in our case, there was a microalveolar pattern formed by hyaline stroma that entrapped a smaller cluster of cells with thicker septa and lack of central loss of cohesion and picket fence-like arrays instead of the classic pseudoalveolar pattern (Figure 8 b) [12]. No rhabdomyoblastic differentiation was seen in our case. In contrast to the alveolar RMS predilection site, the tumor in our case arose in the head and neck region. Moreover, in contrast to the immunohistochemical findings of alveolar RMS, the tumor in our case showed prominent staining for myoD1, with only focal reactivity for myogenin. Unfortunately, molecular testing data were not available to exclude the presence of *PAX-FOXO* fusion genes.

Figure 8. Comparison between alveolar rhabdomyosarcoma (RMS) case and the tumor in the present case. (a) Alveolar RMS with wreath cell (arrow) and thin fibrovascular septa (arrowhead) (H&E, 400×); (b) Sclerosing RMS with a microalveolar structure (H&E, 400×).

Classically, embryonal RMS affects patients of younger age (typically <5 years) with head and neck region and genitourinary predilections, and only few cases involve the extremities [3]. It involves patternless primitive mesenchymal tumors in various stages of myogenesis with variable cellularity and myxoid stroma (Figure 9 a) [3, 11]. Scattered rhabdomyoblasts are often conspicuous (Figure 9 b) [11, 14]. It genetically exhibits 11p15.5 anomaly [7, 9]. Immunohistochemical analysis shows nuclear positive staining for myoD1 [3]. The tumor in our case also occurred in the head and neck region and showed a prominent profile of myoD1 over myogenin immunohistochemically. Although it histologically exhibited an alternating cellular zone, it lacked rhabdomyoblast differentiation and occurred at an older age compared with typical embryonal RMS (Figure 9 c). Unfortunately, molecular testing data were not available to exclude the presence of 11p15.5 anomaly.

Classically, invasive lobular carcinoma of the breast shows discohesive cells arranged in a single-file linear pattern invading the fibrous stroma (Figure 10 a) [15, 16]. Immunohistochemical analysis shows loss of E-cadherin expression [15]. On the other hand, in our case, the tumor cells lacked discohesiveness (Figure 10 b). Invasive lobular carcinoma of the breast is rarely found in children, and it rarely metastasizes to the head and neck region [3].

Figure 9. Comparison between embryonal rhabdomyosarcoma (RMS) case and the tumor in the present case. (a) Embryonal RMS with a marbled appearance (H&E, 25×) (arrow head); (b) Rhabdomyoblastic differentiation in embryonal RMS (H&E, 400×) (arrow); (c) Sclerosing RMS with alternating cellularity zones (H&E, 400×) (star).

Figure 10. Comparison between classical invasive lobular carcinoma of the breast case and the tumor in the present case. (a) Classical invasive lobular carcinoma of the breast shows single-file arrangement (H&E, 400×) (arrow); (b) Sclerosing rhabdomyosarcoma shows a linear pattern (H&E, 400×).

CONCLUSION

Spindle cell/sclerosing RMS is a new variant included in the latest WHO classification. Histopathologically, the tumor might show various growth patterns with abundant hyalinized stroma mimicking other look-alike sarcomas. In this report, several differential diagnoses have been presented, including conventional osteosarcoma, alveolar RMS, embryonal RMS, and invasive lobular carcinoma of the breast. The use of immunohistochemical analysis, especially for myoD1 is important in the confirmation of the diagnosis. Recognition and awareness of the existence of this entity and appropriate use of immunohistochemical analysis are essential to achieve an accurate diagnosis.

ABSTRACT

Primary malignant giant cell tumor of bone (PMGCTB) refers to a high-grade sarcoma arising from adjacent to benign giant cell tumor located in bone tissue. This type of sarcoma is rare and accounts for approximately 7% of all giant cell tumors. This report shares our experience of diagnosing a rare case. A 53-year-old man presented with a mass on the upper end of his tibia that appeared 6 years before he was admitted to the hospital and had no previous history of radiation therapy or surgery. A radiograph showed an aggressive bone tumor at the metadiaphysis with a suspicious femorotibial joint involvement. Histopathology showed mononuclear cell proliferation, multinucleated giant cells with abundant nuclei, identical with mononuclear cells in the stroma, and a high-grade sarcoma area juxtaposition to the benign giant cell tumor. PMGCTBs arise *de novo* and are extremely rare. From these findings, we concluded this case as PMGCTB. Malignant giant cell tumor of bone (MGCTB) prognosis is poor with a 5-year survival of 50%, and PMGCTB has a better prognosis than secondary MGCTB.

Keywords: primary malignant giant cell tumor, high-grade sarcoma, tibia

INTRODUCTION

Jaffe et al., identified giant cell tumor of bone (GCTB) as an entity many years ago and classified it into a primary benign bone tumor that may evolve into a malignant lesion. The etiology of malignant transformation of benign GCTB remains unknown [1-3]. Malignant GCTB (MGCTB) is rare and encompasses 2%–9% of all GCTB. There are only a small number of MGCTB cases published in the literature [4, 5]. In the Cipto Mangunkusumo Hospital, there were two cases reported from 2013 to 2017.

MGCTBs are divided into primary (PMGCTB) and secondary (SMGCTB). PMGCTB is a high-grade sarcoma that presents a *de novo* juxtaposition with conventional giant cell areas. SMGCTB is a high-grade sarcoma that arises at the area previously treated as a conventional GCTB with surgery or radiation. MGCTB diagnosis is challenging because of the variety of malignant tumors containing giant cells. Effective treatment is tough because of the limited existing studies that distinguish PMGCTB, SMGCTB, or post-radiation cancer [4, 5].

The incidence of MGCTB occurs in a wide range of ages, but typically in those 30–55 years of age and more frequently in men with a ratio of 3:1 [6-8]. According to Bertoni F et al., PMGCTB impacts those between 20 and 68 years, whereas SMGCTB impacts those 30–77 years. Both cancers frequently occur in the long bones near the knee joint with 90% of cases located in the meta-epiphyseal segments of the long bones [6, 7].

PMGCTB is extremely unusual and occurs less frequently than SMGCTB. Nascimento et al., reported eight cases, and five cases had been reported by the Mayo Clinic. The most common symptoms of PMGCT are a pain (80%) and swelling (40%) [4, 6]. The radiographic pattern may be identical to conventional GCTB. Most cases are poorly circumscribed. Cortical destruction and soft tissue invasion may occur because of a large area of sarcomatous tissue [9, 10].

Histopathological findings of PMGCTB showed high-grade sarcoma juxtaposed with conventional GCTB areas that are identifiable at the time of the initial presentation. The transition between both components varies considerably. A high-grade sarcoma component includes fibrosarcoma, osteosarcoma, and undifferentiated high-grade pleomorphic sarcoma (UPS) [4-6]. There is a high mitotic activity of both stromal and tumor giant cells, with multiple atypical mitosis present. The prognosis of PMGCTB is still indefinite because of its rareness and short follow-up. Most reports consider the prognosis poor [5, 6].

Here, we report a case of PMGCTB that had a history before the initial presentation and was defined as high-grade sarcomas originating from a giant cell tumor (GCT). The aim of this case report is to define the clinicopathologic and histologic features of malignancy in GCTs.

CASE REPORT

A 53-year-old male presented with a mass on the upper end of his right tibia without a prior history of radiation therapy or surgery. Seven years ago, the patient was in a motorcycle accident that caused a lump on the upper end of his right tibia, but he decided not to go to the hospital. Five years after the accident, the size of the lump remained the same.

One year later, the lump began to grow as large as an egg without pain and made it difficult to walk, but he did not go to the doctor and instead went to a traditional masseur. Five months later, he went to an orthopedic surgeon in Ambon because the lump was getting bigger and was accompanied by pain. He underwent x-ray examination, and the orthopedic surgeon said that there was a benign tumor. He was then referred to the Cipto Mangunkusumo Hospital.

One month later, he went to the Cipto Mangunkusumo Hospital and met the orthopedic surgeon. It was determined that there was a mass on the area below the right knee, which produced serious hemorrhage from the ulcers of the mass, redness, and distal edema. The mass on the right leg was 55 cm in diameter, solid, fixed, and felt warmer than the surrounding tissue (Figure 1). The patient underwent a second x-ray examination and a magnetic resonance image (MRI) while at Cipto Mangunkusumo Hospital (Figures 2 and 3). He also underwent several chest x-rays that showed multiple nodules in both lungs with infiltrates, suggestive of metastasis (Figure 4).

Figure 1. Mass on the upper end of the right tibia.

Figure 2. Plain x-ray of the right knee shows an aggressive tumor at metadiaphysis of the upper end of the right tibia. There is a suspicion that the tumor is also present at femorotibial joint (arrow).

Figure 3. MRI of the right knee shows a mass of solid aggressive tumor, covering epimetadiaphysis of the proximal tibia, femorotibial joint, fibula, and neurovascular anterior tibia (arrow).

Figure 4. The second chest x-ray showed multiple nodules in both lungs with infiltrates suggestive of metastasis.

Fine-needle aspiration was performed, and cytology showed a predominantly necrotic area with fibrous tissue, a few round or spindle cells occurring in clusters, coarse chromatin, and multiple giant cells. From the cytology, we concluded the mass was a bone lesion containing giant cells that cannot be determined to be either benign or malignant (Figure 5). Nine days later, the patient underwent transfemoral amputation of the lower end of the femur. The specimen was sent to the anatomical pathology laboratory. Dissection revealed a solid mass measuring $17 \times 16 \times 11$ cm, white-brown, and firm. The cut section was yellowish,

uncircumscribed, and contained areas of hemorrhage and necrotic tissue. Representative sections were submitted in 22 blocks (Figure 6).

Figure 5. A. Cytology specimen showed round or spindle cells in clusters (Giemsa 100×). B. Multinucleated giant cell (Giemsa 100×).

Figure 6. Mass from the right leg. Note the uncircumscribed yellowish mass with areas of hemorrhage and necrosis.

The histopathological findings showed an area of benign GCT that consisted of mononuclear cell proliferation, and multinucleated giant cells were sparsely spread in the stromal cells. The stromal cells had round, oval, or some spindle-shaped nuclei, with vesicular chromatin and variably prominent nucleoli. There were abundant nuclei of giant cells, which was identical to the mononuclear cells observed in the stroma. There was also a high-grade sarcoma area juxtaposed to the benign GCT. The sarcomatous area consisted of cells with the spindle, pleomorphic, bizarre nuclear, vesicular chromatin, and prominent nucleoli. The cytoplasm was eosinophilic. Mitotic activity was 9–12/10 HPF, and some had atypical features (Figures 7 and 8). Focal reactive bone formations, intravascular invasion, hemorrhage, and necrotic areas were also found (Figure 9). Histological findings were compatible with PMGCTB.

Figure 7. A. The juxtaposition between GCT (on the bottom left) and sarcomatous area (on the upper right, HE 100×). B. Conventional giant cell tumor with scattered multinucleated giant cells (arrow, HE 100×).

Figure 8. A. Atypical mitotic of high-grade sarcoma (HE 400×). B. High-grade sarcoma (HE 400×).

Figure 9. Focal reactive bone formation (arrow) (HE 100×).

After surgery, the patient experienced worsening dyspnea. Cytopathological testing of the sputum was performed and showed a negative result. Three months later, the patient did not receive any chemotherapy due to the long queue, and based on his family, he died because of lung metastasis.

DISCUSSION

In this case, the patient was a 53-year-old male with a mass on the upper end of his right tibia and no history of previous GCT, radiation therapy, or surgery. According to the literature, PMGCTB is a high-grade sarcoma diagnosed during the first treatment for GCTB [4]. PMGCTB typically occurs during the sixth decade of life and more frequently in men [8, 11]. The common sites are at the distal ulna, proximal and distal femur, and proximal tibia (Figure 10) [6], which is consistent with our case.

The x-ray and MRI showed an aggressive bone tumor at the metadiaphysis involving adjacent soft tissue. According to the literature, the radiographic pattern of a PMGCTB may be similar to conventional GCTB. A well-defined lytic lesion involves both the epiphysis and metaphysis. Although well-circumscribed, at least one has a thin cortex and may also be extended or destroyed [9, 11]. Aggressive radiological features such as large soft tissue component or cortical breakthrough may be seen in PMGCTB as well as in SMGCTB and benign recurrences of GCTB. The degree of overlap of the radiological findings in benign and MGCTB makes a histological analysis of tissue critical for diagnosis [8, 12].

Figure 10. Common sites of PMGCTB. A. Distal ulna. B. Proximal femur. C. Distal femur. D. Proximal tibia [6].

FNAB findings, in this case, showed a predominantly necrotic area and fibrous tissue with a small number of round or spindle cells occurring in clusters, coarse chromatin, and multiple giant cells. From the cytology, we conclude that it was a bone lesion containing giant cells that cannot be determined to be either benign or malignant. Giant cell-rich lesions of bone have overlapping cytological features. Therefore, clinical evaluation and radiological findings can help to distinguish these entities and to aid in an accurate diagnosis [13]. In smears showing giant cells and mononuclear cells, it is wise not to make a definitive

diagnosis of GCTB even if suggested by radiological imaging. With regard to the differential diagnosis of other benign tumors with numerous giant cells, full knowledge of clinical and radiographic data is essential for a correct type-specific diagnosis [14].

Gross evaluation, in this case, showed a solid mass that was white-brown and firm. The cut surface was poorly circumscribed and showed a yellowish mass with areas of hemorrhage and necrotic tissue. Macroscopically, PMGCTB usually does not differ from those of GCTB. However, cut sections of PMGCTB typically appear to be soft, and the tumor tissue was focally gray-white and firm, intermixed with hemorrhagic, brownish-red, or a yellowish area of necrosis [4, 11].

Histopathology, this case showed proliferation of mononuclear cells and multinucleated giant cells with abundant nuclei, which was identical to the mononuclear cells in the stromal and a high-grade sarcoma area adjacent to the benign GCT. There were atypical mitoses, some focal reactive bone formation, and intravascular invasion. In the literature, there were distinct areas of typical GCT juxtaposed with a high-grade sarcoma. The high-grade sarcoma included fibrosarcoma, osteosarcoma, and UPS, whereas in this case, the sarcomatous component was UPS. Mitotic activity is always present, and atypical mitosis is also found [4, 6, 11]. Reactive bone can be present focally and should be appropriately identified as not being an integral part of the lesion [15]. It has been previously hypothesized that permeation of GCTB cells into vessels causes some emboli to escape and be lodged in the pulmonary parenchyma and remain viable [16].

The differential diagnosis of PMGCTB is giant cell-rich osteosarcoma, malignant fibrous histiocytoma (MFH) and SMGCTB. The diagnosis of giant cell-rich osteosarcoma requires a component of malignant bone-forming tumor [15]. In MFH, benign GCT areas are not present, and there are multinucleated giant cells with large and pleomorphic nuclei [11]. In SMGCTB, there is a history of GCTB, the recurrence information and remnants of conventional GCTB are visible microscopically [4].

Low incidence of MGCTB made it difficult to determine an appropriate therapy for this case, and the resulting prognosis was poor. Treatment typically includes surgery combined with chemotherapy and radiotherapy. Unfortunately, chemotherapy results are inconsistent but may increase the 5 year survival rate, yet the benefit disappears when most patients reach 5 years post-surgery [5]. The prognosis is poor and many patients die rapidly [4]. In this case, the patient had surgery and had planned chemotherapy, but he never received the latter. He later died within 3 months of the operation.

The limitations of this case report include the lack of concrete evidence that the patient did die. According to several chest x-rays that showed multiple nodules in both lungs with infiltrates, we anticipate that this information was true due to the suggestive metastasis. There was also no histopathological examination of multiple nodules of both lungs, and the sputum smear was negative.

ABSTRACT

Giant cell tumor of bone (GCTB) is a primary bone neoplasm composed of mononuclear cells proliferating among scattered macrophages and large, osteoclast-like giant cells. Secondary malignant GCTB is a sarcoma arising at a site where a GCTB has been previously documented. This case report is about a 32- year-old female who presented with right knee pain of one year duration. The patient had a history of bone tumor, at the same site, six years ago. Radiographs showed a mass in the epimetaphyseal seal, extending into the tibiofemoral and patellofemoral junction. Such findings were consistent with a recurrent lesion. Following microscopic investigation, spindle- cell with atypical mitoses and nuclear pleomorphism, admixed with conventional GCTB, were identified. Sarcomatous changes in malignant GCT develop many years, or even decades, following the primary lesion's removal. Radiologic features are represented by large lesions with cortical destruction and prominent invasion into the soft tissue. Microscopically, the conventional GCTB is adjacent to, or intermixed with, the sarcomatous area. Based on such findings, we conclude this case is a secondary malignant GCTB.

Keywords: giant cell tumor of the bone, secondary malignant

INTRODUCTION

Giant cell tumor of bone (GCTB) is a primary bone neoplasm composed of mononuclear cells proliferating among numerous scattered macrophages and large, osteoclast-like giant cells [1]. It represents around 4% – 5% of all primary bone tumors. Its peak incidence is between the ages of 20 and 45, with a slight predominance in females. In terms of localization, GCTB generally arises at the ends of long bones (e.g., distal femur, proximal tibia, distal radius and proximal humerus). The lesion commonly involves epiphysis and adjacent metaphysis [1-3].

Malignant transformation in GCTB is a rare event. It is classified as primary and secondary [4-6]. Primary malignant GCTB is defined as GCTB composed of sarcomatous growth juxtaposed with zones of typical benign GCTB in an individual without a previous history of surgery or radiotherapy [4-7]. It occurs in 1% – 3% of all GCTB cases [6]. Secondary malignant GCTB is described as sarcomatous growth at the site of a previously documented benign GCT [4-7]. It occurs in 5% – 10% of all GCTB cases [6]. Most secondary malignant GCTBs have a history of irradiation treatment for the primary lesion. Therefore, malignant changes occurring after only surgical procedures represent an extremely rare phenomenon [5, 8].

Histologically, tumors are characterized by many osteoclast-like giant cells, uniformly scattered among numerous oval or plump, spindle-shaped mononuclear cells. The nuclei of mononuclear and giant cells are similar; specifically, they both have round or oval nuclei with regular outlines, evenly distributed fine chromatin, prominent nucleoli, and eosinophilic cytoplasm. Occasionally, a subset of giant cells may present with 50 – 100 or even more nuclei. Mitotic figures are typically observed [1, 9]. Sarcomas are identified based on the presence of atypical mitotic figures and cytological anaplasia in the round or spindle-shaped mononuclear cells associated with conventional GCTB [1, 10].

In the present case report, we describe a 32-year-old female patient with a recurrent bone tumor in the right distal femur. She had an earlier history of bone tumor (in 2009). Upon X-Ray examination, an epimetaphyseal mass in the right distal femur was identified. Histologically, the lesion presented as a high grade sarcoma, consistent with secondary malignant of GCTB.

Secondary malignant GCTB's diagnosis is based on several aspects, such as patient history (age, symptoms, and physical examinations), preferred location, radiographs and histopathology. Secondary malignant GCTB is a rare event. This case report aims to share the experience of diagnosing a rare case.

CASE REPORT

A 32-year-old female presented with right knee pain, which started about one year before evaluation. The patient had a medical history of bone tumor and underwent surgery six years ago. A histopathological examination was not performed. Physical examination of the right

knee showed deformity, shortening, a 2cm leg length discrepancy, external rotation, and a mass. The mass was 8 x 8 x 2cm in size, firm, tender and warm (Figure 1).

X- ray of the right knee showed a plate and screw internal fixation from distal to mid-diaphysis of the right femur in good condition. There was also swelling of the right distal femur soft tissue (Figure 2). An X- ray of the right femur showed a lytic lesion in distal femoral metadiaphysis with thickening of the surrounding soft tissues (Figure 3).

Figure 1. Tumor mass in the right femur (arrow).

Figure 2. An X- ray of the right knee in (a) anteroposterior and (b) lateral views. Plate and screw internal fixation (arrow) and GCT (arrow head) with right distal femur soft tissue swelling (asterisk) are shown.

Figure 3. X- ray of the right femur in (a) anteroposterior and (b) lateral views. Lytic lesion (arrow head) with thickening of surrounding soft tissues (asterisk) are shown.

A CT scan of the right knee showed a right distal femur epimetaphyseal ($6.1 \times 10.2 \times 11$ cm in size), extending into the tibiofemoral and patellofemoral junction, consistent with a recurrent lesion (Figure 4).

Figure 4. A CT scan of the right knee in (a) axial plane and (b) sagittal plane views. The right distal femur epimetaphyseal mass (arrow head), extending into the tibiofemoral and patellofemoral junction, are shown.

Figure 5. Core biopsy of the right distal femur. (a) Giant cells with >20 nuclei (arrow) resemble the stroma cell nuclei (arrow head) (HE 100X). (b) Round/oval nuclei, mild pleomorphic, hyperchromatic and often vesicular with conspicuous nucleoli (HE 400X).

Core biopsy sample revealed tissues contained giant cells with >20 nuclei resembling stroma cell nuclei. The nuclei were round/oval, mild pleomorphic, hyperchromatic, and often vesicular with conspicuous nucleoli. Histological findings were compatible with a giant cell containing lesion, which can be identified in GCTB (Figure 5).

The patient underwent a second surgery one month later. A surgical specimen sized 21 x 14 x 9cm was collected. The cut surface presented as well-circumscribed white mass with solid consistency (Figure 6).

Figure 6. (a) Mass removed from the right knee. (b) The well-circumscribed white mass with solid consistency.

Figure 7. Histological sections of a surgery specimen. (A&B) Conventional GCT area (HE 40X & 400X). (C&D) Sarcomatous area with atypical mitosis (arrow) (HE 40X & 400X).

Representative sections were submitted in 11 cassettes. Histological evaluation revealed tumor tissues contained giant cells with >20 nuclei. There was a similarity among subsets of giant cells and stromal cells nuclei. Nuclei were round/oval, mild pleomorphic, vesicular,

eosinophilic cytoplasm. High cellular stroma were found and arranged in storiform pattern, sarcomatous with oval/spindle nuclei, pleomorphic to bizarre, hyperchromatic, eosinophilic cytoplasm. The mitotic count was 2/10 HPF. Giant cells with bizarre nuclei, lymphovascular invasion, and areas of necrosis were also identified (Figure 7). Histological findings were compatible with high grade sarcoma, which can be found in secondary malignant GCTB.

DISCUSSION

About 70% of GCTB cases are diagnosed in patients 20 – 40 years old, with a peak incidence in the third decade of life [9]. Women are affected about 1.5 times more frequently than men [1, 2, 9]. In line with current reports, the present case involved a 32-year-old female patient.

GCTB is commonly located in the epiphyseal ends of long tubular bones, usually in the distal end of the femur, the proximal end of the tibia, and the distal end of the radius. In the present case, the tumor was at the end of the long bone (right distal femur). Such a location was where the GCTB was previously diagnosed.

GCTB tends to progress to a high grade malignancy. Sarcomatous changes in malignant giant cell tumors can also develop for several years, or even decades, following removal of the primary lesion. Transformation to high grade sarcoma rarely occurs spontaneously. Specifically, it takes place with higher-frequency, post-irradiation therapy [8]. Alternatively, it can occur following a single local recurrence or multiple recurrences. [9] A histological or radiological differentiation between the two is impossible [6]. Clinically, the recurrence of pain and swelling many years post-GCT treatment is a clue of malignant transformation [1, 7]. In the present case, the patient was diagnosed with a bone tumor and underwent the first surgery six years ago, with no histopathological examination. The histopathologic findings from the second surgery, performed one year later, were consistent with high grade sarcoma, corresponding to secondary malignant GCTB. The patient did not have history of irradiation.

GCTB typically occurs as an eccentric, purely lytic lesion involving the end of the bone. It usually extends up to the subchondral bone plate. As a consequence of the tumor growth, the cortex is frequently destroyed. The lesion expands to soft tissues, where it is covered with a thin shell of reactive new bone [2]. Radiologically, a giant cell tumor with malignant change has the features of a large destructive lesion with cortical destruction and prominent invasion into soft tissues.

Plain X-rays of primary malignant GCTB demonstrate the presence of a lytic process extending to the end of the long bone. Imaging rarely shows typical GCT features and sclerotic destructive tumors juxtaposed with it. Plain X-rays of secondary malignant GCTB are characterized by a destructive process, with poor margination, situated at the site of a previously diagnosed GCTB [1]. In the case presented here, an X-ray showed lytic lesions in the distal femoral metadiaphysis, with thickening of the surrounding soft tissues. A CT scan showed a right distal femur epimetaphyseal mass $6.1 \times 10.2 \times 11$ cm in size. The lesion appeared to extend into the tibiofemoral and patellofemoral junction, consistent with a recurrent lesion.

The gross appearance of malignancy in GCT is a large, fleshy tumor often with a soft tissue extension that is commonly seen in sarcomas [1, 2]. In the present case, the tumor's cut

surface showed a well-circumscribed white mass, of solid consistency, with soft tissue extension.

Secondary malignant GCT are a rare condition, defined as a sarcomatous growth that occurs at the site of a previously documented benign GCT [4-8]. Characterised histologically by atypical mitoses and pleomorphism spindle cell nuclear that is next to or intermixed with conventional GCT [9, 11, 12]. Of note, immunohistochemical studies are not required for the transformation's diagnosis [12]. In the present case, a histopathological examination from the first surgery was not available for our review. A core biopsy performed before the second surgery revealed a giant cell containing lesion consistent with GCTB. The histological sections from the second surgery revealed giant cells with >20 nuclei admixed with round and spindle mononuclear cells. Subsets of the giant cells and mononuclear cells' nuclei were similar. In some areas, the spindle stromal component predominated and proliferated. Cells were arranged in storiform pattern with hyperchromatic and pleomorphic to bizarre nuclei. Atypical mitotic, lymphovascular invasion, and necrotic areas were identified. Based on these findings, we conclude that there was a malignant change characterized by sarcomatous growth that occurred next to, or intermixed with, the conventional GCT.

Malignant changes in GCT may be in the form of fibrosarcoma, malignant fibrous histiocytoma, osteosarcoma, or undifferentiated high- grade pleomorphic sarcoma. In an earlier study, Gong et al. reported malignant components, including osteosarcoma (11 cases), undifferentiated, high grade pleomorphic sarcoma (two cases), and fibrosarcoma (four cases) [13]. Additionally, Rock et al. found three times more fibrosarcomas than osteosarcomas among secondary malignant GCTB cases [14]. Bertoni et al. reported osteosarcomas in primary malignant GCTB (four of five cases), osteosarcomas in secondary malignant GCTB (9 of 12 cases), fibrosarcomas (two postradiation secondary malignant GCTBs) and malignant fibrous histiocytomas (one primary malignant GCTB and one postsurgical secondary malignant GCTB) [15]. In the present case, the malignant change was in the form of an undifferentiated high-grade pleomorphic sarcoma.

Secondary malignant GCTB needs to be differentiated from giant cell-rich osteosarcoma. Osteosarcoma's diagnosis requires the presence of a malignant bone-forming tumor [9]. In the present case, no malignant bone-forming tumor was identified.

The prognosis for patients with secondary malignant GCTB is similar to high grade sarcomas. Reports have shown that, in such patients, the prognosis is worse than in those with primary malignant GCTB [1].

The present case report presents a limitation. Specifically, no histopathological examination was performed at the time of the first surgery. However, from the second surgery's microscopic examination, we identified areas of anaplastic pleomorphic tumor cells and atypical mitoses were intermixed with conventional GCT. Such findings were the key in diagnosing malignant changes in GCT [9, 11, 12].

SUMMARY

Malignancy in GCT is a sarcoma arising within the GCT or at the site where a GCT had been previously documented. Malignant transformation in GCTB is rare. Giant cell tumors with malignant changes have radiologic features of large, destructive lesions with cortical

destruction and prominent invasion into soft tissues. Key microscopic features in diagnosing malignant changes in GCT are atypical mitoses and pleomorphism spindle cell nuclear that is next to or intermixed with conventional GCT.

Jakarta, Indonesia

ABSTRACT

Segmental absence of intestinal musculature is a distinct histopathological entity with rare occurrence. The condition typically presents in neonates, with the primary manifestation being intestinal obstruction or perforation. Here we present the case of a neonate who initially presented with a high lesion of anal atresia. In the first few days following colostomy, the infant exhibited signs of intestinal obstruction. An exploratory laparotomy revealed ileal stenosis. A resected ileum specimen showed a narrowed segment of the ileum. Histopathological examination showed focal hypoplasia to total absence of muscularis propria with intact mucosal, submucosal, and serosal layers. Histochemical and immunohistochemical studies confirmed the absence and hypoplasia of muscularis propria, presence of ganglion cells, and absence of Cajal cells in the pathological segment. In cases of neonatal intestinal obstruction due to segmental absence of intestinal musculature, the possibility of defects of intestinal musculature should be investigated, particularly in conjunction with other congenital diseases.

Keywords: congenital defect, segmental absence of intestinal musculature

INTRODUCTION

Segmental absence of intestinal musculature (SAIM) is a distinct histopathological entity with rare occurrence. The condition was reported for the first time in 1943 [1]. Since then, the number of reported cases has been increasing, reaching approximately 25 cases in the English and Asian relevant literature [2]. However, thus far, there have been no such cases reported in Indonesia.

Typically, the condition presents in the neonatal age group, although several cases have been reported in adults [3]. The main manifestation of the disease is intestinal obstruction or perforation, along with other congenital anomalies, such as intestinal atresia, biliary atresia, patent ductus arteriosus, and ventricular septal defect [2, 4, 5]. Patients are mainly admitted to the hospital with complaints of abdominal distention, hypoactive bowel, ileus, and failure to pass meconium [6]. The majority of SAIM cases are discovered through surgery; however, a definitive diagnosis is based on histopathological findings [6]. Following gross examination, several cases demonstrated a thin-walled resected bowel, consistent with wall atrophy with paper-like consistency. Studies have reported an almost translucent color of the resected bowel [1]. Histological findings showed segmental absence or atrophy of intestinal musculature, with normal remaining intestinal layers. Other less common findings include fibrosis, inflammatory infiltration in the pathologic segment, and an underdeveloped capillary network [1,4,7]. The condition may involve the stomach, small intestine, or colon [1].

The pathogenesis of SAIM remains uncertain. However, several theories have been proposed. Abnormality during embryogenesis is thought to lead to incomplete myogenesis. Other theories described an etiology of an ischemic process during pre- or post-natal life, or as part of the remnant of developmental diverticula [2, 8]. Nevertheless, whether the disease is primarily due to malformation, or an ischemic or inflammation process remains controversial [4].

Currently, the condition is not widely recognized among clinicians and pathologists; hence, it is thought that the disease may be underdiagnosed. The aim of this case report was to familiarize pathologists and clinicians with this rare disease.

CASE REPORT

Clinical Summary

A neonate was admitted to Cipto Mangunkusumo General Hospital 20h after birth due to congenital absence of the anal opening. The full-term infant was born through a spontaneous midwife-assisted labor from a mother who underwent irregular prenatal care. There was no record of the Appearance, Pulse, Grimace, Activity, Respiration (APGAR) score; however, the mother stated that the infant cried immediately after birth. The weight of the infant at birth was 3,000g. There were no other congenital anomalies identified at birth. In addition, there was no maternal illness or pregnancy complications reported. The 27-year-old mother denied consuming any medication or herbal drinks during pregnancy other than vitamins prescribed by the midwife. However, the mother revealed a history of untreated leukorrhea during pregnancy. Both parents did not report a family history of congenital anomalies. The older

sibling of the patient was aged 5 years and born without any congenital anomalies or complications during pregnancy and labor.

At the time of hospital admission, physical examination showed normal vital signs with pale acral. It was observed that the abdominal distention with an abdominal circumference of 34cm, exceeded the normal limit (Figure 1) [9]. Laboratory testing showed a slight increase in leucocyte count ($24,400/\mu\text{L}$) and prolonged prothrombin time/activated partial thromboplastin time ($1.46\times/1.57\times$). Abdominal X-ray and babygram examination confirmed the diagnosis of a highlesion of anal atresia.

Figure 1. The patient presented with abdominal distention 20h after birth.

Figure 2. Radiological examination performed at the time of hospital admission. (a) Babygram imaging. (b) Abdominal X-ray examination in the knee-chest position.

The colon and small bowel were distended and filled with fecal mass (Figure 2a, 2b). The early babygram did not reveal ileal atresia. The initial diagnosis was anal atresia with suspicion of late-onset neonatal sepsis.

At the age of 2 days, the patient underwent colostomy. In the first few days following surgery, the patient developed signs and symptoms of intestinal obstruction, such as vomiting, abdominal distention, and decreased production of stoma. The intestinal obstruction became apparent on day 8. The patient was lethargic and serum markers of inflammation increased. The levels of C-reactive protein and procalcitonin were 16.4 and 0.44, respectively. Repeated abdominal X-ray examinations showed intestinal dilatation, indicating the presence of high intestinal obstruction. Subsequently, an exploratory re-laparotomy was performed. Intraoperative findings revealed ileal stenosis, located 120cm from the Treitz ligament. Evaluation of the colostomy stoma did not demonstrate obstruction or presence of pus. Adhesion between the ileum and sigmoid was found. A 2.5-cm specimen of the ileal stenosis was resected, and an ileo-ileal anastomosis and adhesiolysis were performed. Post-operative abdominal X-ray examination did not show signs of intestinal obstruction. Post-operative laboratory testing showed a decrease in the level of C-reactive protein from 16.4 to 10.9; however, the level of procalcitonin was slightly increased from 0.44 to 0.54. There was no vomiting reported, and the production of colostomy stoma was within normal limits. Several days following the surgery, an enteral diet was initiated. The patient was discharged from the hospital 19 days after surgery. During subsequent outpatient visits, the patient did not show signs of recurring intestinal obstruction. Moreover, the stoma output was within normal limits. Unfortunately, the patient was lost to follow-up after a few months.

Pathological Findings

Histopathological examination was performed using a resected specimen of the ileum (2.5cm in length and 1cm in diameter). The specimen revealed a narrowing segment of the ileum (Figure 3). Histopathological examination showed intact mucosa with a normal to shortened ileal villous. The lamina propria to serosal layers were mildly infiltrated with chronic inflammatory cells, neutrophils and eosinophils of 5–10 per high-power field. Muscularis propria showed focal hypoplasia to total absence of smooth muscle fibers. There were no vascular network abnormalities, vasculitis, or ischemic changes present (Figure 4).

Figure 3. Gross examination showed a narrowing segment (red arrow) of the resected ileum. (a) Serosal surface and (b) Luminal surface.

Histochemical and immunohistochemical staining was performed for further assessment of both the muscle fibers and innervation of the ileum. Gomori trichrome staining showed normal connective tissue fibers in both the normal and stenotic segments of the bowel. Smooth muscle actin showed positivity in the smooth muscle, in terms of normal thickness

and hypoplastic muscle. CD117 immunostaining was non-reactive, thus revealing the absence of Cajal cells in both segments where the muscularis propria were hypoplastic and absent. Calretinin, which was positive in normal ganglion cells, showed normal submucosal and myenteric ganglion cells in the narrowed segment and revealed slightly hyperplastic ganglion cells in the normal segment (Figure 5, 6).

Figure 4. Histopathological examination. (a) Relatively normal segment of the ileum (HE, 40 $\times$). (b) Focal hypoplasia of the muscularis propria (hematoxylin & eosin [HE], 40 $\times$). (c) Focal hypoplasia of the muscularis propria (HE, 100 $\times$). (d) Total absence of the muscularis propria (HE, 40 $\times$). b-d. Intact mucosal, submucosal, and serosal layers.

Figure 5. Histochemical and immunohistochemical staining in the total absence of muscularis propria. (a) SMA, 40 $\times$; (b) CD117, 40 $\times$; (c) Calretinin, 100 $\times$ and (d) Gomori trichrome, 40 $\times$.

Figure 6. Histochemical and immunohistochemical staining of the hypoplastic muscularis propria. (a) SMA, 40 $\times$; (b) CD117, 40 $\times$; (c) Calretinin, 100 $\times$ and (d) Gomori trichrome, 40 $\times$.

DISCUSSION

Neonatal intestinal obstruction commonly results in admission to the Neonatal Intensive Care Unit. The incidence rate is approximately 1 in 2,000 live births [10]. The cardinal signs of this condition are polyhydramnion, bilious emesis, failure to pass meconium in the first 24–48 hours of life, and abdominal distention [10, 11]. The blockage along the gastrointestinal tract may be structural or functional [11, 12]. Structural obstruction includes atresia, stenosis, intussusception, volvulus, intussusception, hernias, bands, and presence of masses [11]. In contrast, functional obstruction can be caused by Hirschsprung's disease, sepsis, electrolyte imbalance, meconium plug syndrome, and other secondary conditions that lead to loss of peristaltic activity [11, 13]. The most common cause of intestinal obstruction in newborns is intussusception (20.8%), followed by intestinal atresia (11.8%) [14]. Among intestinal atresias, jejunoileal and anal atresia are the most common conditions, with an incidence rate of 1 in 5,000 live births [10]. Initial treatment involves nasogastric decompression, fluid resuscitation, and administration of broad-spectrum antibiotics. Most cases usually require non-emergent operative repair, except for malrotation and volvulus. However, surgical management should proceed promptly [10].

On the other hand, gastrointestinal perforation in newborns exhibits a slightly higher incidence rate of approximately 0.6% in the neonatal intensive care unit [15]. However, the exact incidence rate is yet to be determined. The mortality rate remains high (30–50%), despite the development of antibiotics and surgical procedures [15, 16]. The leading cause of gastrointestinal perforation in newborns is necrotizing enterocolitis (NEC), which occurs in approximately 1–3 per 1,000 live births [12]. Other causes of perforations are sepsis,

intestinal obstruction, iatrogenic trauma, Hirschsprung's disease, and spontaneous intestinal perforations [15].

SAIM is a rare condition that mainly occurs in neonates and presents with other congenital anomalies, such as patent ductus arteriosus, ventricular septal defect, intestinal atresia, and biliary atresia [1, 2, 4]. The main manifestation of this disease is a progressively acute abdomen due to bowel obstruction or perforation. Patients are admitted to the hospital with complaints of moderate-to-severe abdominal distention, diminished bowel sounds, failure to pass meconium, and bilious vomiting [17]. The incidence of SAIM is difficult to determine due to its rarity. In the neonatal age group, the age of onset ranges from 1 to 99 days. Davis *et al.* reported five cases of SAIM, all of whom were born preterm through cesarean section, with very low-birth-weight ranging from 490g to 1166g [17]. The majority of preterm neonates with SAIM also present with respiratory distress syndrome [4]. Although typically present in neonates, studies have also reported the occurrence of SAIM in adults. There is no sex predilection of this defect in adults. The age of onset ranges from 26 to 64 years, with a higher incidence reported in the older age group [3]. Two studies reported a family history of congenital anomalies, such as congenital megacolon and osteogenesis imperfect [3, 18].

In the present case, the clinical presentation was similar to that observed in other reported cases, with regards to chief complaints, age of onset, and correlation with other congenital anomalies. The patient was admitted to the hospital primarily due to anal atresia. Abdominal distention was also reported at the time of admission. An initial diagnosis of bowel obstruction was considered due to the anal atresia. However, abdominal distention, vomiting, and the absence of stoma production persisted after colostomy. These signs and symptoms led to the diagnosis of intestinal obstruction, which was located proximally to the stoma. According to the history of pregnancy, the patient was born full term, with a birth weight within normal limits (3,000g). This may raise awareness among clinicians, as most reported neonatal cases occur in preterm, low-birth-weight infants. This case shows that full-term infants with a normal birth weight may also harbor a congenital defect.

Following gross examination, the resected SAIM showed a thin-walled bowel, with paper-like consistency [3]. Investigators have reported several cases exhibiting segments of intestine with an almost translucent color [1]. Therefore, intraoperative transillumination is recommended as part of the diagnostic process [1, 17]. In this case, intraoperative findings and gross examination of the resected small intestine showed a narrowing segment of the ileum that manifested as an intestinal obstruction. Macroscopically, the observed atrophic intestinal wall was consistent with findings reported in previous studies. Unfortunately, transillumination was not performed during surgery.

Nawar and Sawyer stated that all the cases they reviewed showed a gradual or abrupt loss of the muscularis propria of both the longitudinal and circular layers. Inflammation and mesenteric vessel thrombosis are uncommon findings. Approximately half of the cases demonstrated loss of nerve plexuses in affected segments [3, 19]. Our histopathological findings showed segmental hypoplasia to total absence of the muscularis propria, with remaining intact mucosal, submucosal, and serosal layers. There were mild inflammatory cell infiltrations within the lamina propria. However, vasculitis, thrombosis, or signs of vascular anomaly were not identified. Moreover, there was no fibrosis found in the area of the defect. Innervation was found to be normal. Submucosal and myenteric plexuses were observed in both normal and pathological segments. These findings are consistent with previous results

reported in the literature. The diagnosis of SAIM was reached solely based on pathological evaluation.

SAIM may mimic other conditions that manifest as obstruction or perforation. In the presence of obstruction, the closest differential diagnoses are Hirschsprung's disease and intestinal atresia. In the presence of perforation, SAIM may also mimic NEC and intestinal ischemia. Both Hirschsprung's disease and SAIM may cause delay in passing meconium and colonic dilatation. Hirschsprung's disease is diagnosed by the absence of ganglion cells and hypertrophied nerve fibers [12]. SAIM, on the other hand, involves the presence of ganglion cells and absence of muscularis propria. Intestinal atresia varies from a septum obstructing the bowel (i.e., membranous atresia) to a complete gap between the bowel ends with a mesenteric defect and apple-peel atresia [12,14]. However, SAIM may cause dilatation or stenosis of the bowel, while maintaining the continuity of the bowel. However, several articles reported cases of SAIM, which were found in close proximity to intestinal atresia [14, 20]. Therefore, it is possible that both entities share a similar etiology. NEC accounts for the majority of intestinal obstructions occurring in newborns. Therefore, it is the closest differential diagnosis for SAIM, which manifests as perforation. However, NEC shows signs of inflammation, bacterial overgrowth, epithelial regeneration, mucosal edema, and ischemic transmural necrosis [21]. Notably, SAIM shows limited signs of inflammation. The pathology of intestinal ischemia involves mucosal damage, neutrophil infiltration, neuronal damage, and degeneration of muscle, which includes clear cytoplasm, pyknotic nuclei, and apoptotic bodies [22]. In the present case, there was no mucosal damage or acute inflammatory cells identified. The remaining muscularis propria in the hypoplastic segment was normal.

Considering that the clinical presentation of SAIM may mimic other conditions, exploratory laparotomy is the gold standard, and the diagnosis is mainly dependent on histopathological findings. Resection of the affected intestines, ileostomy, and end-to-end anastomosis have been linked to favorable outcomes. Of note, most patients are not in good general condition at the time of diagnosis due to the presence of peritonitis. Therefore, they usually require initial enterostomy [17]. The incidence of SAIM is currently unknown; thus, determining the prognosis of this disease is challenging. Davis *et al.* did not report progression or secondary perforation in five cases of neonatal SAIM [17]. Additionally, Nawar and Sawyer did not report the recurrence of intestinal perforation in adults with SAIM [3]. However, Oyachi *et al.* reported the occurrence of multiple perforations after resection. This condition is caused by unstable mesenteric circulation, which leads to ischemic process and infarction at previously unresected SAIM lesions [5]. Considering that the diagnosis of SAIM lesions during surgery is occasionally challenging, a frozen section procedure may be a useful diagnostic modality to avoid misdiagnosis. Surgeons should ensure that the resection margins are free of lesions prior to performing an end-to-end anastomosis. Preoperative diagnosis of SAIM is not possible; therefore, it is important for surgeons to understand this condition in order to recognize the lesions during surgery and prevent secondary destruction of the muscle layer.

CONCLUSION

In cases of neonatal intestinal obstruction or perforation, the possibility of defects of intestinal musculature due to SAIM should be investigated, especially in conjunction with other congenital diseases.

HEMANGIOMA-LIKE VESSELS IN THE RESECTION MARGIN OF GIANT HEMANGIOMAS OF THE LIVER AS A POSSIBLE CAUSE OF RECURRENCE: A CASE SERIES AND LITERATURE REVIEW

***Marini Stephanie^{*}, Ening Krisnuhoni, Diah Rini Handjari
and Nur Rahadiani***

Department of Anatomical Pathology, Universitas Indonesia/
Cipto Mangunkusumo Hospital, Jakarta-Indonesia

ABSTRACT

Most liver hemangiomas are small and asymptomatic, but large, or giant, hemangiomas may be symptomatic and can occur with hemangioma-like vessels (HLVs) distant from the primary tumor. We report three cases of giant cavernous hemangioma of the liver in adults, with the hemangioma recurring in one of the three patients 8 months after surgical resection. All cases had clusters of HLVs located far from the primary tumor and in the resection margin.

Keywords: giant hemangioma, liver, recurrence, hemangioma-like vessels

INTRODUCTION

Cavernous hemangioma of the liver is the most common benign liver tumor with an estimated incidence ranging from <1% to 20%. It can occur at any age but is most frequently found in young adult women. Increased size may be related with sex hormones. Liver hemangiomas are generally solitary, with only about 10% being multiple. Cavernous hemangiomas can vary in size from a few millimeters to so large that they can replace most of

^{*} Corresponding Author's Email: marini2sh@gmail.com.

the liver. However, the majority are <4 cm and are usually asymptomatic. Gross sections have a spongy appearance with a lot of blood. Cavernous hemangiomas rarely become malignant, and usually, surgical resection is indicated for large tumors or those that progress. Hemangiomas can have irregular margins that extend between liver cells at the edge of tumor. The presence of small clusters of hemangioma-like vessels (HLVs), located distant from the tumor mass associated with giant hemangioma may be the reason for post-resection recurrence. We report three cases of giant cavernous hemangioma of the liver in adults, one of which recurred after surgical resection [1, 2].

CASE REPORT

Case 1

A 46-year-old man came to the Cipto Mangunkusumo Hospital complaining of intermittent stomach pain for 3 weeks before admission. The patient had a 6-year history of stomach discomfort; however, he noted an enlargement of the stomach accompanied by nausea and fatigue 1 year ago. Enlargement of the abdomen without jaundice was found on physical examination. Abdominal computed tomography (CT) scan showed a hypodense $14 \times 16 \times 20$ -cm lesion involved segments V, VI, VII, and VIII, with enhancement in the arterial phase that increased in the venous and delayed phases, consistent with a hemangioma.

Gross examination following hepatectomy revealed a well-demarcated $15 \times 14 \times 8$ -cm tumor (Figure 1). The cut surface had a spongy appearance, and tissue sections contained a lot of dark blood, with some areas appearing yellow-white. Microscopic examination showed spaces and vascular channels of varying sizes that were separated by a fibrous matrix, lined by flattened endothelial cells. Organizing thrombi and wide fibrotic areas were observed. The interface between the lesion and the adjacent liver parenchyma was irregular, and many hemangioma-like vessels (HLVs) were seen in the resection margin.

Figure 1. A. Abdominal CT scan, venous phase. B. Macroscopic appearance of the right lobe resection of case one. C. Microscopic appearance of the cavernous hemangioma of case one (HE, $\times 40$); D. Irregular, spongy interface (Trichrome $\times 100$); E. Resection margins with hemangioma-like vessels (HLVs) (Trichrome $\times 100$).

A follow up abdominal CT scan performed 8 months after resection revealed a $5.4 \times 5 \times 5$ -cm nodule in the posteromedial right lobe segment VIII. Afterwards the second surgical resection was done to the patient. In intraoperation, a new growth was noted in the post-resection site, and gross examination revealed a $6 \times 4 \times 3$ -cm tumor with microscopic features similar to those of the previous tumor with hemangioma-like vessels (HLVs) in the resection margin. Trichrome staining of the interface border revealed a tumor margin with an irregular, spongy interface. Immunohistochemistry was negative for Ki-67.

Case 2

A 53-year-old woman came to the Cipto Mangunkusumo Hospital complaining of enlargement of the abdomen for 1 year before admission, accompanied by nausea, vomiting, and weight loss over the previous 6 months. Physical examination found no jaundice and a palpable mass with indistinct edges in the right hypochondria. An abdominal CT showed a $15.8 \times 12.8 \times 15.3$ -cm hypodense mass in the right lobe of the liver, segments IV, V, VII, and VIII with enhancement in the arterial, venous, and delayed phases, consistent with hemangioma. A follow-up CT scan 6 months after transarterial embolization found necrosis with no significant change in the size of the mass. Following hepatectomy, gross examination revealed a $20 \times 13 \times 9$ cm tumor (Figure 2). The cut surface had a spongy appearance and tissue sections contained a lot of dark blood and some areas that were yellow-white in color. Microscopic examination showed spaces and vascular channels of varying sizes lined by flattened endothelial cells and separated by a fibrous network including dispersed thrombi. The interface between the lesion and adjacent live parenchyma was irregular and hemangioma-like vessels (HLVs) were seen in the resection margin. Trichrome staining of the interface border revealed a tumor margin with a predominantly irregular and spongy interface and an interdigitating pattern. Immunohistochemistry was negative for Ki 67.

Figure 2. A. Abdominal CT scan, venous phase; B. Macroscopic appearance of right lobe resection of case two; C. Microscopic appearance of the cavernous hemangioma of case two (HE, $\times 100$).

Case 3

A 41-year-old woman came to the Cipto Mangunkusumo Hospital complaining of stomach bloating for 2 months before admission. Physical examination found no jaundice and a solitary palpable mass with indistinct edges in the right hypochondria. An abdominal CT showed a $10.16 \times 9.3 \times 26.67$ -cm multilobulated mass with irregular edges involved liver

segments V, VI, VII, and VIII that displaced the intestine medially. There was contrast enhancement in the arterial and venous phases and patchy areas of enhancement within the mass, consistent with liver neoplasm and a differential diagnosis of hemangioma and hepatocellular carcinoma. The gross appearance of the hepatectomy specimen revealed a $22 \times 16 \times 9$ -cm tumor (Figure 3). The cut surface had a spongy appearance and tissue sections contained a lot of dark blood and some areas that were cystic or yellow-white in color. Microscopic examination showed spaces and vascular channels of varying sizes lined by flattened endothelial cells and separated by a fibrous network including dispersed thrombi. The interface between the lesion and adjacent live parenchyma was irregular and hemangioma-like vessels (HLVs) were seen in the resection margin. Trichrome staining of the interface border revealed an interdigitating pattern. Immunohistochemistry was negative for Ki 67.

Figure 3. A. Abdominal CT scan, venous phase; B. Macroscopic appearance of right lobe resection of case three; C. Microscopic appearance of cavernous hemangioma of case three (HE, $\times 400$).

DISCUSSION

The ages of these three patients with cavernous hemangiomas of the liver ranged from 41 to 53 years old. Patients came in a state of advanced may have contributed to the large size of the tumors [2]. All three were found in the right lobe of the liver, and a size of more than 10 cm surpassed the 5 cm needed consideration as a giant hemangioma [1-3]. The ages of a series of 198 cases of hepatic hemangioma reported by Etemadi et al. ranged from 27–84 years. Most were located in the right lobe, and only 18,2% were from 5 to 25 cm in size. Of the 129 who could be followed-up, 7% were treated by surgical resection because of abdominal pain, large size, rupture, or bleeding [4]. The lack of response to arterial embolization in case two is consistent with a report by Koszka et al. that arterial embolization to restrict the growth of a 40 cm giant liver hemangioma was not effective and was followed by a worsening of symptoms [5].

The gross and microscopic appearance of the resected tumor was similar in all three cases and in line with a previous report of the pathological characteristics of the interface border of the tumor and liver parenchyma by Zimmermann et al. [6].

In a previous report, Zimmermann et al. have described four distinct interface patterns that were seen in cavernous liver hemangiomas [6]. Pattern A was characterized by a capsule-like fibrous lamella (fibrous interfaces). In pattern B, the peripheral component of the hemangioma interdigitated with the liver parenchyma, dilated vascular channels were associated with remnants of the portal tract, and a fibrous lamella was absent (interdigitating

interfaces). Pattern C included a compressed interface with a thin, vascular tissue layer that separated the tumor and liver parenchyma without the presence of a fibrous lamella or interdigitating vascular channels. Pattern D was a, irregular, spongy interface with a highly irregular border characterized by the presence of liver parenchyma located between dilated vascular channels. Of the 10 cases in their report, 7 showed predominantly pattern A, and with 5 of the 10 exhibiting a single pattern and the remaining 5 a mixed pattern. Only two hemangiomas had a predominant pattern D. Trichrome staining of tissue from our patients revealed that the interface border in case one and two had a predominant pattern D with a highly irregular border and lack of a clear separated of tumor and non tumor tissue. Case three had a pattern B interdigitating interface. Immunohistochemistry was done to exclude a diagnosis of low-grade angiosarcoma, with Ki67 staining of low- and high-grade angiosarcomas as controls.

Case one had the longest follow-up, with recurrence detected on CT at 8 months after hepatectomy. Previously, Conter et al. have reported four cases of recurrence of hepatic hemangiomas, with two of them recurring years after surgery in patients with histories of long-term hormonal therapy [7]. Romano et al. have described a case with three hepatic hemangioma recurrences in the years after surgery in a patient with no history of hormonal therapy [8]. The pathological evaluation of the resection margins or hemangioma-like vessels (HLVs) was not reported in either of those cases. Zhu et al. reported two cases of giant hepatic hemangiomas that recurred 4 and 5 years after resection. Both had irregular interfaces because of the presence of hemangioma-like vessels (HLVs). No hormonal therapy data were reported [9]. Etemadi et al. have reported post-surgical recurrences in three of 198 patients with hepatic hemangioma, but the time of recurrence, pathology data on the resection margin, and the presence of hemangioma-like vessels (HLVs) were not reported [4]. Our case had a short recurrence time, and the tumor, which occurred in the area of the original hepatectomy, had hemangioma-like vessels (HLVs) in the resection margin. The patient did not have a history of hormonal therapy. However, whether HLV in the resection margin or hormonal therapy contributed to the recurrence remained unclear. All three of our patients had hemangioma-like vessels (HLVs) in the margin but only one experienced a recurrence.

CONCLUSION

Three cases of giant liver hemangiomas had hemangioma-like vessels (HLVs) in the resection margin, two had highly irregular interfaces but only one had a short recurrence time.. However, whether hemangioma-like vessels (HLVs) at the resection margins, an irregular interface, or hormonal therapy contribute to recurrence is not clear.

46, XX OVOTESTICULAR DISORDER OF SEX DEVELOPMENT, HISTOPATHOLOGICAL VIEW: REPORT OF A RARE CASE

***Intan Nevita Oktamiya Bernanthos
and Budiana Tanurahardja****

Department of Anatomical Pathology, Faculty of Medicine,
Universtas Indonesia/Dr. Cipto Mangunkusumo Hospital, Jakarta, Indonesia

ABSTRACT

Ovotesticular disorder of sexual development (OT-DSD) is a rare congenital anomaly characterized by the simultaneous presence of ovarian tissue with mature ovarian follicles and testicular tissue with distinct seminiferous tubules in the same individual. The most common karyotype of OT-DSD is 46, XX. A 12-year-old boy was brought by his parents to our hospital because of a mass in his right groin area that had enlarged over the past 2 weeks. The patient's medical history included multiple surgeries due to hypospadias and unilateral right-side cryptorchidism. Histopathological analysis revealed the presence of ovarian tissue containing multilocular cysts and uterine tissue with an endometrium component, but no testicular component. Hormone analysis showed elevated levels of luteinizing hormone and follicle-stimulating hormone, with normal levels of testosterone and anti-Müllerian hormones. The patient was diagnosed with 46, XX OT-DSD and assigned as a male.

Keywords: ovotesticular disorder of sexual development, 46, XX DSD

INTRODUCTION

Disorder of sex development (DSD) is a rare congenital condition associated with a disagreement between chromosomal, gonadal, and phenotypic sex [1]. Generally, DSD is divided into disorders of the sex chromosomes (such as Klinefelter and Turner syndrome), hormone synthesis or action (such as congenital adrenal hyperplasia), and gonadal development (such as XY gonadal dysgenesis, XX testicular DSD, and ovotesticular DSD (OT-DSD)) [2]. The incidence of DSD is reportedly 1:4500 in newborns with ovotesticular disorders accounting for less than 10% of cases [3]. Disorders of gonadal development with the 46 XX karyotype include testicular DSD, ovotesticular DSD, gonadal dysgenesis, and premature ovarian failure [4].

OT-DSD, formerly known as true hermaphroditism, is a rare congenital anomaly characterized by the simultaneous presence of ovarian tissue with mature ovarian follicles and testicular tissue with distinct seminiferous tubules in the same individual, which accounts for 3%-10% of all cases of DSD. The most common karyotype is 46, XX (60%), followed by chromosomal mosaicism/chimerism (33%), and the 46, XY karyotype (7%) [4-7]. OT-DSD most commonly occurs in XX and XX/XY, but rarely XY individuals, and typically presents in infancy as a range of atypical genitalia.

Generally, clinical manifestations of OT-DSD include ambiguous genitalia, isolated clitoromegaly, perineal hypospadias, and cryptorchidism. Phenotypical males complain of breast development, periodical hematuria, or cryptorchidism. Patients with the female phenotype present with menstrual disorders or clitoromegaly, and more rarely with cyclic pain emanating from a descended or undescended gonad [8].

Ovotesticular DSD is usually detected in infancy as underdeveloped genitalia. The etiology of 46, XX ovotesticular DSD is heterogeneous and may be related to mosaicism or genetic mutations. Most cases (65%) are negative for the sex determining region of the Y chromosome (SRY). XX ovotesticular DSD lies in the spectrum of testicular DSDs. Although the genetic etiology of 46, XX testicular and ovotesticular DSD may be the same, it is critical to detect the presence of ovarian tissue for optimal management [6].

Here, we report a rare case of 46, XX ovotesticular DSD with emphasis on its pathological aspects and clinical significance to increase the awareness of this entity.

CASE REPORT

In December 2016, a 12-year-old boy was brought by his parents to our hospital due to the presence of a mass in his right groin area that had enlarged over the past 2 weeks. The mass caused no pain, redness, or itching. The patient's medical history included multiple genital surgeries due to hypospadias (penoscrotal type) and unilateral cryptorchidism in his hometown and in a hospital in Malaysia, as well as repair urethroplasty due to abnormal erections and urine leakage. There was no remarkable family history or parental consanguinity. The patient was fully alert with stable vital signs. The patient's body weight was 33.5 kg, height of 140 cm, and body mass index of 17.09 kg/m² (-1<z score<0). A physical examination showed bilateral breast enlargement. An examination of the external

genital examination revealed enlargement of the right testicle (6 × 4 cm), while the size of the left testicle was normal.

Laboratory results showed no elevation in either β -human chorionic gonadotropin or alpha-fetoprotein serum levels (0.100 IU/L and 0.8 IU/mL, respectively). A chromosomal examination using Giemsa banding showed that the karyotype of the patients was 46, XX (Figure 1). SRY gene detection was performed for this patient. Testicular ultrasound revealed multiple cystic lesions and septation of the enlarged right scrotum, but not the left (Figure 2).

Figure 1. Chromosome analysis results. Giemsa banding of a peripheral blood sample revealed that the karyotype of the patients was 46, XX (46 chromosomes with XX sex chromosomes). There was no major structural abnormality.

Figure 2. Testicular ultrasound. A. Multiple cystic lesions with septa of the right scrotum. B. The left testis appeared to be solid.

Figure 3. Gross appearance of the right testis. A. Mass with a smooth muscle surface. B. Cut section showing areas with multiple cysts.

The patient was scheduled for explorative surgery. Following identification of the right testicular mass, right orchiectomy was performed. Macroscopically, the tumor was encapsulated with a smooth external surface, measuring 8.5 × 5.0 × 3.5 cm, and gray in color. On a cut section, the tumor appeared to have multiple cysts containing serohemorrhagic fluid with diameters ranging from 0.1 to 4.5 cm. A histopathological examination revealed the presence of ovarian tissue containing multilocular cysts of various sizes, lined by granulosa cells, as well as uterine tissue with the endometrial component lined by ciliated columnar cells, accompanied by endometrial glands arranged in tubular patterns. There was no testicular component of the tissue. The histological findings were consistent with ovarian tissue with follicle cysts and uterine tissue with endometrial cells (Figure 4).

The results of a postoperative hormonal assay showed increased levels of luteinizing hormone (LH), 10.5 mIU/mL (normal 1.7-8.6 mIU/mL) and follicle-stimulating hormone (FSH), 19 mIU/mL (normal 1.5-12.4 mIU/mL), with normal levels of estradiol (5.00 pg/mL; normal range, 5-20 pg/mL), testosterone (159 ng/mL; normal range, 64.9-778 ng/mL), anti-Müllerian hormone (AMH) (26.37 ng/mL; normal range, 3.8-159.8 ng/mL), and dehydroepiandrosterone sulfate (34.7 µg/dL; normal range, 24.4-247 µg/dL). The postoperative serum levels of alpha-fetoprotein and β-human chorionic gonadotropin were within normal limits (0.8 IU/mL and 0.1 IU/L, respectively).

Follow-up visits were then scheduled. The urethrocutaneous fistula and webbed penis were addressed by urethroplasty and penile reconstruction at 6 months after presentation. A tissue sample of the left testicle collected during surgery had a Müllerian duct remnant with extensive squamous metaplasia and ovarian tissue with primary follicles (Figure 5). A repeat urethroplasty was performed within 6 months for repair of recurrent urine leakage. After surgery, erections were normal with no more urine leakage. The patient also underwent breast reduction surgery. Histological analysis of the breast revealed that the tissue was consistent with gynecomastia (florid type) with ductal epithelial hyperplasia, tufting, micropapillary patterns, and increased periductal stromal cellularity (Figure 6).

After psychiatric consultation and evaluation, the patient and his parents decided that the patient was a boy. The patient then continued with hormonal therapy and was scheduled for a routine follow-up.

Figure 4. Histopathological examination of ovarian tissue with primary follicles and multilocular cysts, varying in size, lined by granulosa cells and uterine tissue with an endometrial component lined by ciliated columnar cells, with tubular ductus. No testicular tissue was observed. (A) Hematoxylin and eosin (H&E) staining, $\times 40$. (B) H&E, $\times 100$. (C) H&E, $\times 40$. (D) H&E, $\times 100$.

DISCUSSION

DSD is rare congenital condition associated with a disagreement between chromosomal, gonadal, and phenotypic sex with an incidence of 1:2000-5.500 live births due to multifactorial etiologies. The Chicago nomenclature divides the condition into six groups (Table 1). The current etiological classification of DSD according to the 2006 consensus of the Lawson Wilkins Pediatric Endocrine Society (LWPES) and the European Society for Pediatric Endocrinology (ESPE) is dependent on adrenal or gonadal involvement and karyotype analysis [1].

Table 1. DSD classification according to the 2006 LWPES/ESPE consensus

Cases	Previous nomenclature	New nomenclature
	Intersex	DSD type
1.	Congenital adrenal hyperplasia	46, XX DSD
Cases	Previous nomenclature	New nomenclature
	Intersex	DSD type
2.	Male pseudohermaphrodite	46, XY DSD
	Undervirilization of an XY male	
	Undermasculinization of an XY male	
3.	Female pseudohermaphrodite	46, XX DSD
	Overvirilization of an XX female	
	Masculinization of an XX female	
4	True hermaphrodite	Ovotesticular DSD
5.	XX male or XX sex reversal	46, XX testicular DSD
6.	XY sex reversal	46, XY, complete gonadal dysgenesis

Embryologically, the genital and urinary systems have the same origin. The development of the gonads (testes and ovaries) begins at around gestational week (GW) 4 by the formation of urogenital ridges originating from the intermediate mesoderm. From the urogenital ridge cells, two cellular masses evolve successively toward transitional embryonic kidneys (pronephros and mesonephros) and the definitive embryonic kidneys (metanephros). The mesonephros consists of the mesonephric (or Wolffian) ducts and the paramesonephrics (or Müllerian) ducts (Figure 7) [1].

Early gonadal differentiation is controlled by various genetic factors (Figure 7). At GW 7, the transcription factor SRY, mapped to Yp11.2 (with only one exon), is activated, while other genes (essentially SF-1, WT1, and CBX2) promote male gonadal development. SRY, also known as testis-determining factor, promotes the transformation of the primary sex cords to testes. Around GW 8, the male-specific hormones testosterone and AMH are produced. Testosterone secreted by Leydig cells promotes the development of the internal genital tract in the male, which consists of the epididymis, vas deferens, seminal vesicles, and ejaculatory ducts. On the other hand, AMH secreted by Sertoli cells induces regression of the paramesonephric ducts and inhibits development of the female internal genitalia [1].

Figure 7. (Continued).

OT-DSD is a very rare sexual differentiation disorder in infants born with the internal reproductive organs (gonads) of both sexes and is characterized by the presence of ovarian tissue with mature ovarian follicles and testicular tissue with distinct seminiferous tubules in the same gonad (ovotestis) [5, 7, 8]. However, as time passes, the ovarian tissue usually becomes functional and the testicular tissue regresses becoming dysgenetic and showing interstitial fibrosis and lack of spermatogonia [2]. Our patient was diagnosed with suspected OT-DSD as an infant based on a gonadal biopsy that revealed the presence of ovarian tissue, but no testicular tissue. Even though there was no histopathological finding of testicular tissue, the elevated levels of testosterone and AMH supported the presence of functional testicular tissue in this patient.

The types of gonads observed in OT-DSD patients are ovotestis (44%), ovary (33%), and testis (22%). Depending on the type and laterality of the abnormal gonad, OT-DSD is classified into three types: unilateral (ovotestis on one side and a normal gonad on the other side), bilateral (both gonads are ovotestis), and lateral (one gonad is a testis and the other is an ovary) [8]. In our patient, both gonads were composed of ovarian tissue.

Various types of chromosomal abnormalities have been described in OT-DSD, including 46, XX; 46, XY; 46, XX/46, XY, and 45, X/46, XY [5, 8-10]. Most cases of ovotesticular DSD are sporadic [8]. Genetically, the karyotype of our patient was 46, XX and there was no remarkable family history.

Clinical features of OT-DSD include ambiguous genitalia, isolated clitoromegaly, perineal hypospadias, and cryptorchidism. Phenotypical males complain of breast development, periodical hematuria, or cryptorchidism. Patients with a female phenotype present with menstrual disorders or clitoromegaly, and more rarely with cyclic pain emanating from a descended or undescended gonad [8] (Figure 8), while hormonal levels are typically normal. Patients with OT-DSD have some degree of function and therefore normal levels of FSH, LH, estradiol, and DHT [11]. In the present case, all hormonal levels were normal. The clinical presentations of OT-DSD often go undetected until adolescence when phenotypic males are evaluated for gynecomastia or testicular cysts, which are treated surgically [13].

The diagnosis of OT-DSD is suggested by a mosaic karyotype, but is confirmed by the presence of ovarian and testicular tissue on biopsy [14]. Based on detection of the SRY gene, 46, XX DSD can be clinically classified as SRY-positive or -negative. SRY-positive individuals usually have normal male genitalia, small azoospermic testes, and hypergonadotropic hypogonadism. These characteristics have also been reported in some 46, XX males (testicular DSD). The SRY-negative group includes patients with OT-DSD, which is characterized by the presence of both testicular and ovarian tissues in the gonads of the same individual. Testicular DSD is characterized by the full development of both gonads as testis without any evidence of ovarian tissue [12]. The diagnosis of OT-DSD is based on the exclusion of other DSDs. The differential diagnosis includes mixed gonadal dysgenesis, 46, XX testicular DSD, and premature ovarian failure (Table 2).

Microscopically, with OT-DSD, the ovary is usually normal (prepubertal ovary with primordial follicles and primary oocytes with a few primary or antral follicles, prepubertal testis with immature seminiferous tubules lined by immature Sertoli cells and primitive germ cells, usually without spermatogonia). Ovotestis is characterized by normal ovarian tissue with atrophic testicular tissue [15] (Figure 9).

Figure 8. Approach for ambiguous genitalia.

Figure 9. Clinical and pathological aspects of OT-DSD. (A) External male genitalia are hypoplastic with a penile clitoris, hypoplastic labia, and vaginal vestibule. (B) Ovotestis of a child. The ovarian parenchyma forms a cap over the testicle, which is attached by a pedicle. (C) Ovotestis of a child. A gonad with two parts separated by a connective septum. The upper zone shows the ovarian parenchyma overlying the testicular parenchyma. Among some seminiferous tubules, primordial follicles can be identified. (D) Numerous primordial follicles without maturation set in an abundance of spindle cell stroma. (E) Testicular parenchyma rich with cellular stroma similar to ovarian stroma. Some seminiferous tubules are markedly hypoplastic. (F) Epithelial cords with irregular shapes and microliths. Underneath the surface, these cords are embedded in ovarian-like stroma.

Table 2. Differential diagnosis of ovotesticular DSDs [10, 15]

No.	Diagnosis	Common features	Different features	Karyotype	Picture
1.	Mixed gonadal dysgenesis	Cryptorchidism, pubertal masculinization. Asymmetric gonadal differentiation	Ovarian tissue, if present, lacks primordial follicles; internal/external genitalia are not relevant to differentiate these two conditions. Elevated FSH	45, X/46, XY, 45, X/46, XX or 45, X/47, XXY; may also have 46, XX but missing part of one X chromosome	 (Top) Streak tissue and rete are separated by the tunica albuginea of the testis. (Bottom) Prepubertal patients develop normal immature testis during puberty with tubules exhibiting mild hypospermatogenesis to total sclerosis. The streak gonad has ovarian stroma without primordial ovarian follicles. The streak ovary has primordial follicles and primitive sex cord-like structures with or without germ cell components within the ovarian type stroma, mimicking gonadoblastoma and tumors composed of granulosa or Sertoli cells.

Table 2. (Continued)

No.	Diagnosis	Common features	Different features	Karyotype	Picture
2.	46, XX testicular DSD	Gynecomastia, cryptorchidism, hypospadias ambiguous genitalia	No ovarian tissue	46, XX	 Testicular parenchyma with marked fibrosis of most of the seminiferous tubules, alternating with other tubules lined only with Sertoli cells. Leydig cells are also present.
3.	Premature ovarian failure	46, XX	Sex steroid deficiency and elevated of serum gonadotropins before the age of 40 years [16]	46, XX	 Premature ovarian failure shows dense cortical stroma lacking primordial or developing follicles. This appearance was seen throughout the ovary.

The extent of follicular maturation, the corpora lutea, and corpora albicantia varies with OT-DSD. The seminiferous tubules, which rarely contain developing sperm cells, often have Sertoli cells only with a dysgenetic appearance that frequently undergo hyalinization. Sertoli cells are positive for immunostaining of inhibin and maintain the expression of D2-40, which is indicative of immaturity. Many Sertoli cells are negative for the androgen receptor [8] (Figure 10).

Prognostic factors are important to assign gender as soon as possible (before the age of 2-4 years), since there are usually no other developmental anomalies and patients will have a better chance for normal psychological, sexual, and reproductive lives if the gonad inappropriate for gender assignment is removed. Dysplastic gonads are at risk for developing germ cell malignancy and an increased risk for gonadal malignancy if a Y chromosome is present [15].

Figure 10. Immunostaining in OT-DSD. (A) Inhibin immunostaining of an ovotestis. Seminiferous tubules are highlighted by inhibin staining, which is also expressed by the immature ovarian follicles. (B) The seminiferous tubules and Leydig cells were positive for inhibin immunostaining. Seminiferous tubules are immature and malformed. (C) Immature and malformed seminiferous tubules as well as the peritubular stroma are positive for D240 immunostaining. (D) Androgen receptors are scarcely expressed in Sertoli cells or even absent in some seminiferous tubules, in contrast with the strong expression in peritubular and interstitial cells.

Treatment of OT-DSD is complex because it requires expertise in several subspecialized fields. Also gender assignment should be based on the functional potential of the phenotype. The discordant gonads should be removed as early as possible. In males, the testicular tissue

is preserved and orchiopexy is performed. The incidence of testicular tumors in males ranges from 1 to 10%, which are predominantly gonadoblastomas and dysgerminomas, thus long-term surveillance is needed. Hypospadias repair is also required for such males. Males also tend to require hormonal replacement therapy because of progressive testicular fibrosis [14]. The incidence of gonadal tumors is approximately 3% in 46, XY OT-DSD and rare in 46, XX OT-DSD [15].

A 56-YEAR-OLD WOMAN WITH AN ELEVATED PARATHORMONE LEVEL AFTER THE SURGERY FOR SECONDARY HYPERPARATHYROIDISM

Caglar Keskin and Mustafa Şahin

Ankara University School of Medicine, Ankara, Turkey

A 56-year-old women presented with generalized bone pain and itching. In laboratory test parathyroid hormone levels was found to be 1470 pg/ml. In the patient's past medical history she had been undergoing *hemodialysis since* 2000 for chronic kidney disease secondary to pyelonephritis. In 2006, she admitted to our hospital with multinodular goiter and high parathyroid hormone level (PTH: 1088 pg/ml) and then she had bilateral subtotal thyroidectomy for nodular goiter and parathyroidectomy. She has no history of neck irradiation. Pathological examination was consistent with 16 mm oncocytic variant papillary thyroid cancer and right parathyroid nodular hyperplasia. There was not thyroid capsular invasion. After the surgery radioiodine therapy had not been given because of re-surgery plan. Serum thyroglobulin and antithyroglobulin antibody measurement was found 1.78 ng/ml and 1274 IU/ml respectively. Throid function tests were within the normal range and the patient was not using levothyroxine. During the follow-up parathyroid hormone levels has been remained high and calcium level was normal. In 2009 hypoechoic lesion with 05x06 mm diameter was seen in right thyroid bed in thyroid sonography. In the same ultrasonographic examination did not revealed parathyroid adenoma and parathyroid scintigraphy also revealed no pathological findings. At that time in laboratory tests, PTH, calcium and phosphate level was found 1440 pg/ml, 8.6 mg/dl and 6.4 mg/dl respectively. In 2011 the patient was treated with cinacalcet but after the three months treatment was discontinued because of continued epistaxis. Coagulation analyses were within normal ranges. Previously renal hemorrhage has been reported due to cinacalcet [1].

End stage renal disease (ESRD) patients with secondary hyperparathyroidism (HPT) are at greater risk of thyroid cancer [2]. It is not clear if thyroid cancer in these patients is more aggressive. Specific immunological functional defects may be responsible in part. In addition to relation between primary hyperparathyroidism and thyroid cancer. Secondary hyperparathyroidism may also be related to thyroid cancer.

DEXA scan results was consistent with osteoporosis (femur neck T-score:-4.8, lumbar spine total T-score:-3.7)

Recommended target values for serum PTH (150–300 pg/ml) in secondary hyperparathyroidism [3]. Parathyroidectomy is not required for patients with a mild form of secondary hyperparathyroidism. Parathyroidectomy is generally required for severe secondary hyperparathyroidism which are not controlled by medical therapy. Especially young patients with precisely localized lesion in sonography evaluation [4, 5, 6].

There is no consensus or guideline on the treatment and the radioactive iodine dosages that should be administered in end stage renal disease patients. Empirically 40-50 % of routine doses would be enough in such patients. It is better to perform dialysis sessions immediately before and at 48 hours after ¹³¹I administration [7]. Also there is no specific recommendation for TSH suppression in these patients.

EPILEPSY SURGERY AND TECHNICAL ASPECTS OF INVASIVE MONITORING

Jorge A. González-Martínez, MD, PhD

Epilepsy Center, Neuroscience Institute, Cleveland Clinic

KEY POINTS

- To discuss the clinical indications for invasive monitoring for medically intractable epilepsy.
- To understand the advantages and disadvantages of the subdural method
- To understand the advantages and disadvantages of the SEEG method
- To discuss specific indications for different methods of invasive monitoring

INTRODUCTION

Epilepsy surgery aims for the complete resection (or disconnection) of the cortical and subcortical brain areas responsible for the generation and primary organization of the epileptic clinical activities (epileptogenic zone). The epileptogenic zones (EZ) may eventually overlap with functional (eloquent) cortex, which must be preserved in most of the patients. In order to define the anatomical location of the EZ and its proximity with possible cortical and subcortical eloquent areas, an array of non-invasive tools are available: analysis of seizure semiology, video-scalp electroencephalographic recordings (ictal and interictal recordings), neuropsychological testing, magnetoencephalography (MEG) and MRI [4, 22, 28]. In addition Neuroimaging techniques may provide functional (ictal single-photon-emission computed tomography [SPECT] and fMRI) as well as metabolic information (magnetic resonance spectroscopy [MRS] and positron emission tomography [PET]). These methods are usually complementary and will define hypothetical cortical zones of interest as the symptomatogenic, irritative, ictal and functional deficit zones, in addition to the EZ. When the non-invasive data is insufficient to precisely define the location of the hypothetical EZ,

when there is the suspicious for early involvement of eloquent cortical and subcortical areas or when there is the possibility for multi-focal seizures, invasive monitoring may be indicated [1, 16, 17, 38].

This chapter discusses the technical aspects, clinical indications and the role of invasive monitoring in medically refractory focal epilepsy, focusing on subdural electrodes and stereoelectroencephalography-(SEEG).

LOCALIZING THE EPILEPTOGENIC ZONE

In most cases of focal medically intractable epilepsy, data generated from non-invasive EEG recordings and other electrophysiologic/neuroimaging techniques are sufficient to approximate the location of the epileptogenic zone [9, 28, 32, 37]. Prolonged video-scalp EEG monitoring, in conjunction with analysis of clinical semiology, remains the gold standard for diagnosis and localization of epileptogenic zone [22]. This non-invasive sampling technique gives an excellent overview of the location and extent of the epileptogenic areas but quite often only approximates the boundaries of both the irritative and epileptogenic zones. Scalp EEG detects only epileptiform activity that results from EEG synchronization of large areas of cortex, estimated in some studies to be between 6 and 8 cm², and recordings are disturbed by the smearing effect of bone and other high-resistance structures (e.g., meninges and scalp) between the cortical generators and the recording electrodes [12, 22]. Magneto-encephalography (MEG) may overcome some of these problems, with better identification of the epileptic activity localized in a tangential orientation (as the interhemispheric fissure, opercular areas, etc.) but still providing limited information regarding the interictal epileptic activity [19]. In specific pathological groups as malformation of cortical development (MCD), between 85% and 100% of patients with MCD exhibit epileptiform discharges on interictal scalp EEG recordings ranging from lobar to lateralized, non-localizing to diffuse (including generalized spike-wave patterns in some cases of subependymal heterotopia [23, 29, 30]. The spatial distribution of interictal spikes is usually more extensive than the structural abnormality as assessed by intraoperative inspection or MRI visual analysis [20, 23]. For these reasons, when subtle forms of cortical dysplasia are suspected as the pathological substrate of medically intractable epilepsy, mainly in patients with extra-temporal epilepsy and non-lesional imaging, extra-operative monitoring is indicated [1, 13, 14, 24].

LOCALIZATION OF THE FUNCTIONAL/ELOQUENT ZONE

Localization of functional areas in the brain, and the anatomical boundaries of these areas with the EZ is an essential part in the process of developing an adequate and individualized surgical strategy [5, 22, 37]. In malformations of cortical development (MCD), because most the pathological substrate are often localized in the frontal lobe (therefore in potentially eloquent cortex), an understanding of the functional status of the involved region(s) and its anatomical and pathological correlations are essential [18, 21, 37]. Some focal MCD lesions characterized by significant FLAIR signal increase on MRI and located in anatomically

functional areas (e.g., primary motor, Broca area) are not functional on direct electrical stimulation, and the same lesions showed no evidence of intrinsic epileptogenicity as assessed through mapping of the ictal onset zones [36]. On the other hand, MCD lesions with mild or no FLAIR signal increase were functional and at times epileptogenic. These results agree with previous observations that eloquent function persisted in MCD devoid of balloon cells [24, 41]. Similar EcoG patterns were reported in patients with low-grade glial tumors (e.g., dysembryoplastic neuroepithelial tumor and ganglioglioma), whereas dysplastic and epileptic cortical areas were found immediately surrounding these lesions [6]. Functional cortex may therefore be displaced within the same hemisphere and have direct implications on the options for epilepsy surgery. Therefore, the precise anatomical location of eloquent cortex located in the vicinity or within the limits of the hypothetical EZ is essential information that will guide the surgeon in performing a safe and efficient surgical strategy, which has, as ultimate goal, a sustained seizure control status with no neurological deficits. Among the several invasive methods used for the diagnosis and treatment of medically intractable epilepsy, the subdural method likely provides the more precise and detailed functional mapping data from the superficial cortical areas.

THE SUBDURAL METHOD

Chronic intracranial recordings were initially reported in 1939 when Penfield and colleagues used epidural single contact electrodes in a patient with an old left temporal-parietal fracture and whose pneumoencephalography disclosed diffuse cerebral atrophy [2]. Subsequently, the use of subdural grid arrays became more popular after multiple publications during the 1980s demonstrated their safety and efficacy [11, 22, 40]. Before that time most invasive techniques involved epidural electrodes or intraoperative recordings.

Indications, Advantages and Disadvantages of Subdurals

The most common indications for intracranial electrodes include lateralization or localization of epilepsy and localization of functional/eloquent cortical information. In the first case, preoperative non-invasive studies and semiology often suggest focal epilepsy but scalp electroencephalography is unable to adequately localize or lateralize the epileptogenic zone. Subdural grids have particular advantages: they can be in place long enough to record both spontaneous seizures and interictal activity during various stages of arousal, and they have superb applicability for mapping of cerebral function extra-operatively. These characteristics allow tailored cortical resections around areas of higher function while minimizing the risk of permanent neurological deterioration. *Extra-operative mapping with the subdural method (which here includes subdural grids and strips) has the main advantage of allowing an optimal coverage of the subdural space adjacent cortex with adequate and continuous superficial functional mapping capabilities* [17, 24, 25, 26]. Intra-operative electrocorticography, as compared with chronically implanted subdural grids, is a limited option because it only provides information restricted to interictal activity. When used in patients under general anesthesia, it is believed that anesthetic agents may influence EEG

activity by altering the thresholds of after discharges and motor responses creating a misleading electroencephalographic picture [1]. Additionally, intraoperative functional mapping often requires a cooperative patient that can tolerate being awake during surgery under local anesthesia. This is particularly difficult in the pediatric population.

Subdural grids has many disadvantages, including surgical risks, financial costs, and limitations in the ability to access deep cortical regions. Because foreign bodies are inserted into the cranial vault, the risks of the procedure include wound infection, flap osteomyelitis, acute meningitis, cerebral edema, and hemorrhage [21, 27, 33]. Concerns about increased intracranial pressure may reduce the maximal number of electrodes that can be inserted and therefore produce incomplete epileptic mapping from large cortical areas. Other limitations may include the anatomic location of the proposed area of sampling (e.g., mesial orbitofrontal, anterior cingulate gyrus) and “re-do” surgeries with cortical adhesions. Other limitations of subdural grid implantation are the number of available channels for recording with the EEG system in the hospital. Some systems can handle only 64 channels unlike other systems, which can record up to 200 channels thus allowing the implantation of more electrodes over wider cortical areas. Despite this, only limited coverage of cortical regions can be sampled and preoperative surgical planning is necessary to maximize the chances of covering the ictal onset zone with the electrodes. *One of the main disadvantages of the subdural methodology is the incapacity of exploring deep cortical areas*, as the depths of sulci, opercular, interhemispheric, mesial temporal structures and insula [35]. Depth electrodes implanted using a non or semi-stereotactic technique can partially compensate these deficiencies [7].

Subdural Implantation Technique

Subdural electrodes (stainless steel or magnetic resonance-compatible platinum) electrodes, embedded in strips or sheets of polyurethane or other synthetic material, are implanted over the suspected epileptogenic or functional dysplastic regions. Variability in shape and size of the electrodes permits tailoring their use to the specific clinical situation. Custom designed arrays of subdural electrodes have been configured for placement in specific anatomical locations. For example, to record from interhemispheric brain regions, rows of electrodes arranged in curvilinear fashion were designed to follow the curvature of the corpus callosum. Subdural grids are inserted through either open craniotomy incisions or burrholes and registered stereotactically for extraoperative mapping. The cortical covering may extend beyond the visualized cortical area, as grids may be slid over the edges of the craniotomy to cover adjacent areas for better EcoG or functional sampling. Besides the EcoG recordings and direct electrical stimulation studies, grids can be used to record somatosensory evoked potentials after stimulation of the trigeminal (lip) or median nerves for central sulcus localization.

All patients that are offered subdural grid electrode implantation for monitoring have previously undergone the standard pre-operative evaluation. Decision for invasive monitoring is made during a multidisciplinary meeting, including neurologists, neurosurgeons, neuroradiologists and neuropsychologists. Areas of coverage are determined based on pre-operative non-invasive studies including scalp EEG, ictal SPECT, PET, MEG, and at times, sphenoidal electrodes. Incision and craniotomy should allow for placement of electrodes in

addition to the anticipated area of resection. Positioning of the patient should allow for stereotactic guidance in the event that depth electrodes are to be placed during the same operation. As part of our surgical protocol, peri-operatively antibiotics, dexamethasone, and mannitol (0.25 g/kg) are given. The incision should be large enough to allow for a sizable craniotomy. Usually a T-shaped or large question mark incision is used. If basal temporal coverage is needed, the incision should extend down to the zygoma. Orbitofrontal coverage can be easily achieved as long as the incision allows for visualizing the key hole and turning a flap just above this level. Inter-hemispheric coverage necessitates an incision to midline. In order to facilitate placement of electrodes, the basal and mesial surfaces should be carefully inspected for cortical draining veins that will impede placement of electrodes. Using bayoneted forceps, and under a constant stream of irrigation, the grid electrodes can be slid into place. Any resistance likely indicates impedance from a draining vein and the trajectory of the grid should be adjusted.

Prior to covering lateral cortex, the depth electrodes are inserted using stereotactic guidance. The entry point should be in the middle of a gyrus, avoiding sulci, with a trajectory that is as perpendicular to the cortical surface as possible. The parenchyma serves to anchor the electrode in place. Using the wand to find the trajectory from the entry point, the pial surface is incised and the electrode inserted. Once the depth electrodes are in place, the grids for lateral coverage can be inserted. Again using bayoneted forceps, the larger grid electrodes are laid over the cortical surface, tucking the edges under the borders of the dural flap. Once in place, each electrode wire is secured to the nearest dural edge with a stitch. The remaining closure is performed using standard neurosurgical technique (Figure 1).

Figure 1. Intra-operative aspect of subdural grid implantation in patient with extra-temporal epilepsy and non-lesional MRI. The picture shows a large right side temporal-parietal occipital craniotomy with placement of large 8X8 subdural grid at the dorsal-lateral convexity of the posterior quadrant region and multiple strips in the subtemporal, frontal and mesial occipital areas. Depth electrodes were implanted in the temporal and frontal lobes.

The Stereo-Electroencephalography (SEEG) Method

The SEEG method was developed and popularized in France by Jean Tailarach and Jean Bancaud during the 50's and has been mostly used in France and Italy, as the method of choice for invasive mapping in refractory focal epilepsy [5, 10, 29]. The principle of SEEG is based on anatomic-electro-clinical correlations, which takes as the main principle, the 3-dimensional spatial-temporal organization of the epileptic discharge within the brain in correlation with seizure semiology. The implantation strategy is individualized, with electrode placement based on a pre-implantation hypothesis that takes into consideration the primary organization of the epileptiform activity and the hypothetical epileptic network involved in the propagation of seizures. For these reasons, the pre-implantation hypothesis has a paramount importance in the strategic placement of the electrodes. If the pre-implantation hypothesis is incorrect, the placement of the depth electrodes will be inadequate and the interpretation of the SEEG recordings misleading. According to several European and recent North-American reports, *SEEG methodology enables precise recordings from deep cortical and subcortical structures, multiple non-contiguous lobes, as well as bilateral explorations while avoiding the need for large craniotomies* [3, 9, 14, 35].

The SEEG technique was originally described as a multi-phase and complex method, using the Talairach stereotactic frame and the double grid system in association with teleangiography [34, 37]. Despite its long reported successful record, with almost 60 years of clinical use, the technical complexity regarding the placement of SEEG depth electrodes may have contributed to the limited widespread application of the technique in centers outside Europe. Taking advantage of new radiological and computational innovations, commonly available in many surgical centers, more modern and less cumbersome methods of stereotactic implantation of depth electrodes can be applied in routine basis.

Indications, Advantages and Disadvantages of SEEG

In addition to the general indications for invasive monitoring, specific indications can be considered to choose SEEG in detriment to other methods of invasive monitoring. These criteria included:

1. The possibility of a deep-seated or difficult to cover location of the EZ in areas such as the mesial structures of the temporal lobe, opercular areas, cingulate gyrus, interhemispheric regions, posterior orbito-frontal areas, insula and depths of sulci.
2. A failure of a previous subdural invasive study to clearly outline the exact location of the seizure onset zone.
3. The need for extensive bi-hemispheric explorations.
4. Presurgical evaluation suggestive of a functional network involvement (e.g. limbic system) in the setting of normal MRI.

In these scenarios, the SEEG methodology may be considered as a more efficient and safer option. As mentioned above, the SEEG methodology has the advantages of allowing extensive and precise deep brain recordings and stimulations with minimal associated morbidity. In re-operations, mainly in patients who underwent a previous subdural evaluation,

possibilities are that the majority of these patients failed epilepsy surgery because of difficulties in accurately localizing the EZ. These patients pose a significant dilemma for further management, having relatively few options available. Further open subdural grid evaluations may carry the risks associated with encountering scar formations, and still having limitations related to deep cortical structure recordings. A subsequent evaluation using the SEEG method may overcome these limitations, offering an additional opportunity for seizure localization and sustained seizure freedom [35]. *The main disadvantage of the SEEG method is the more restricted capability for performing functional mapping.* Due to limited number of contacts located in the superficial cortex, a contiguous mapping of eloquent brain areas cannot be obtained as in the subdural method mapping. In order to overcome this relative disadvantage, the functional mapping information extracted from the SEEG method is frequently complemented with other methods of mapping, as DTI images or awake craniotomies [14].

Technique of SEEG Implantation

The development of an SEEG implantation plan requires the clear formulation of a specific anatomo-electro-functional hypothesis to be tested. This hypothesis is typically generated during the patient management conference and is based on the results of the various non-invasive evaluation tests. In this decision-making process, the respective significance of pre-surgical evaluation testing may vary greatly, depending on each patient. After an anatomical and functional localizing hypothesis is formulated, a tailored implantation strategy is planned, with the goal of confirming or rejecting the pre-implantation hypothesis. In this phase, the exploration is focused to sample the anatomic lesion (if present), the more likely structure(s) of ictal onset and the possible pathway(s) of propagation of the seizures (functional networks). The desired targets are reached using commercially available depth electrodes in various lengths and number of contacts, depending on the specific brain region to be explored. The electrodes are implanted using conventional stereotactic technique through 2.5 mm diameter drill holes. Depth electrodes are inserted using orthogonal or oblique orientation, allowing intracranial recording from lateral, intermediate or deep cortical and subcortical structures in a three-dimensional arrangement, thus accounting for the dynamic, multidirectional spatiotemporal organization of the epileptic pathways.

As part of our routine practice, the patient are admitted to the hospital the day of surgery. The day before surgery, a stereo contrasted volumetric T1 sequence MRI is performed. Images are then transferred to our stereotactic neuronavigation software (iPlan Cranial 2.6, Brainlab AG, Feldkirchen, Germany) where trajectories are calculated the following day. The day of surgery, while the patient is under general anesthesia, the Leksell stereotactic frame (Elekta, Stockholm, Sweden) is applied using standard technique. Once the patient is attached to the operating table with the frame, a stereo dyna CT is performed. The pre-operative MR images and the stereo dyna CT are then digitally processed using a dedicated fusion software (syngo XWP, Siemens Healthcare, Forchheim, Germany). These fused images are used during the implantation procedure to confirm the accuracy of the final position of each electrode and to insure the absence of vascular structures along the electrode pathway, which weren't previously noted with the contrasted MRI. Following the planning phase using the stereotactic software, trajectories' coordinates are recorded and transmitted to the operating

room. Trajectories are in general planned in orthogonal orientation in relation to the skull's sagittal plane in order to facilitate implantation and later on interpretation of the electrode positions. Using the Leksell stereotactic system, coordinates for each trajectory are then adjusted in the stereotactic frame and a fluoroscopic image, in lateral view, is performed in each new position. If the specific trajectory is aligned correctly, the implantation is then continued, with skull perforation, dura opening, placement of the guiding bolt (AdTech, Racine, WI, USA; Integra, Plainsboro, NJ, USA) and final insertion of the electrode under fluoroscopic guidance. The electrode insertion progress is observed under live fluoroscopic control in a frontal view to confirm the straight trajectory of each electrode. For additional guidance a coronal MRI slice corresponding to the level of each electrode implantation is overlaid to the fluoroscopic image.

Figure 2. SEEG methodology. Picture showing the SEEG implantation technique with the stereotactic placement of depth electrodes (A); post-operative X-ray with electrodes placed in orthogonal and oblique fashion in the right temporal, parietal and insula regions (B); Final aspect of right side SEEG implantation (C); Post operative imaging processing with three dimensional representation of the brain anatomy and the implanted SEEG electrodes (D).

A post-implantation dynaCT scan is performed while the patient is still anesthetized and positioned in the operating table. The reconstructed images are then fused with the MRI dataset using the previously described fusion software. The resulting merged datasets are displayed and reviewed in axial, sagittal and coronal planes allowing the verification of the

correct placement of the electrodes [14]. After surgery, patients are transferred to the epilepsy monitoring unit (EMU). The duration of admission at the epilepsy monitoring unit varies from patient to patient, depending on several factors including number, quality and ictal and interictal patterns of recordings. The average, length of stay of patients in the EMU who underwent SEEG implantation is 7 days (range from 3 to 28 days). After obtaining the necessary information electrodes are removed in the operating room, in a procedure performed under local anesthesia and sedation. Patients are discharged next morning and resective surgery is scheduled 2-3 months following SEEG electrodes removal (Figure 2).

Invasive Monitoring Morbidity

In the recent SEEG series, the total complication rate varies from 3% to 5% [9, 14]. Other groups reported similar results. Cossu et al reported a morbidity rate of 5.6%, with severe permanent deficits from intracerebral hemorrhage in 2 patients (1%). In the Cleveland Clinic reported series, all 3 complications were hemorrhagic, which has been reported in several studies to be the most common complication in depth electrodes placement [14]. Other published series reporting complications across invasive monitoring procedures (subdural grids and depth electrodes) reported rates ranging from 0% to 26% [27, 21, 39]. Interestingly, subdural monitoring with grid electrodes has historically been shown to have low permanent morbidity (0 to 3%) compared with depth electrodes (3-6%) since there is no intraparenchymal passage. Although it is difficult to compare morbidity rates between subdural grids and SEEG due to the variability in patient selection, different institutions and variable number of implanted electrodes, it is our preliminary impression that the SEEG method provides at least a similar degree of safety when compared with subdural grids or strips. This impression is also shared by others [8, 10, 15].

CONCLUSION

The goals of invasive monitoring in refractory focal epilepsy may include (1) the need for better anatomical delineation of the hypothetical epileptogenic zone and (2) the need for the definition of cortical and subcortical functional brain areas. Extra-operative mapping with the subdural method (which here includes subdural grids and strips) has the advantage of allowing an optimal coverage of the subdural space adjacent cortex with adequate and continuous superficial functional mapping capabilities. In addition, from a surgical perspective, subdural implantations are open procedures, with better management of possible intracranial hemorrhagic complications. The disadvantages of the subdural method are related to the incapacity of recording and stimulating from deep cortical and subcortical areas, as the insula, posterior orbito-frontal, cingulate gyrus, depths of sulci, etc. In these scenarios, the SEEG methodology may be considered as a more efficient and safer option. SEEG has the advantages of allowing extensive and precise deep brain recordings and stimulations with minimal associated morbidity.

Chapter 357

PERIOPERATIVE VISUAL LOSS AFTER SPINE SURGERY

Mariel Manlapaz, MD and Sree Kolli, MD

Anesthesiology Institute, Cleveland Clinic, Cleveland, Ohio

KEY POINTS

- The post-operative vision loss (POVL) is rare but a very a devastating complication.
- The ischemic optic neuritis (ION) is the main cause of POVL
- Maintaining optimum ocular perfusion pressure and keeping the eyes free from pressure are the main factors to prevent POVL
- Avoidance hypotension and anemia are helpful to maintain ocular perfusion pressure.
- The use of colloids more than crystalloids solutions are helpful to reduce the increase in intraoculr pressure during spine in prone position.

INTRODUCTION

Perioperative visual loss (POVL) is a rare, unexpected, but devastating complication that can occur in patients undergoing spine surgery. The incidence of POVL is approximately 1/60,000 to 1/125,000 of all general anesthetics [1, 2] However the risk of POVL is believed to be significantly greater following cardiac surgery and spine surgery. First described by Hollenhorst in 1954 [3], there have been numerous reports since, establishing a clear link between spine surgery in the prone position and POVL. Research on POVL is limited due to its rare occurrence and consists largely of case reports [6-7]. A recent review by Shen and colleagues of 5.6 million patients from the National Inpatient sample (NIS) found the incidence of POVL to be 3.09/10,000(0.03%) after spinal fusion and 8.64/10,000 (0.09%) after cardiac surgery. The actual rate of POVL may be even higher after spine surgery, with incidence rates ranging from 0.094% [4] to 0.2% [8].

ETIOLOGY

Although the etiology of POVL is not properly understood, multiple risk factors have been proposed that includes decreased ocular perfusion pressure, excessive blood loss and anemia, hypotension, hypoxia, excessive fluid replacement, elevated venous pressure, head positioning and patient-specific vascular susceptibility [10]. POVL occurring with spine surgery may result from anterior ischemic optic neuropathy (AION), posterior ischemic optic neuropathy (PION), central retinal artery occlusion (CRAO), cortical blindness and posterior reversible encephalopathy (PRES). According to the American Society of Anesthesiologists (ASA) postoperative visual loss registry, the most common cause of POVL in spinal procedures are the two different forms of ischemic optic neuropathy: AION and PION, accounting for 89% of the cases. [9], of which 60% is due to PION and 11% due to CRAO.

Most recent NIS review suggests gender plays an important role with men being at higher risk of POVL after spinal fusion relative to women (odds ratio OR of 1.75). Age appears to be a risk factor too, with those aged 50-64 years displaying an increased risk (OR 1.75). Another unexplained finding was that children under 18 years age had the highest overall risk for POVL (OR 6.91), which was primarily attributed to cortical blindness rather than AION/PION and may represent a different etiology. POVL is also noted to be significantly increased in hip and femur operations (1.86/10,000 or 0.19%). These procedures share several features including large blood loss, hemodynamic perturbations, high embolic loads, and significant inflammation.

A recent multicenter case-control study by the Postoperative Visual Loss Study Group, explored the risk factors for ION after spinal fusion surgery in the prone position [11]. They compared 80 cases from the ASA Postoperative Visual Loss Registry to 315 controls from 17 institutions throughout the United States overcoming the limitations of the previous small studies. [4, 5, 49]. Obesity, male sex, Wilson Frame use, longer anesthetic duration, greater estimated blood loss, and decreased percent colloid administration were significantly and independently associated with ION after spinal fusion surgery [11].

ANATOMY

Basic knowledge of the blood supply to the optic nerve is important to understand POVL, especially ION. The Ophthalmic artery, originating from the internal carotid artery and its various branches is the principal blood supply to the retina, globe and optic nerve. The central retinal artery, a division of the ophthalmic artery supplies the inner retina.

The anterior part of the optic nerve has a rich arterial supply mainly from the posterior ciliary artery (PCA), except for the surface nerve fiber layer which is supplied by the retinal circulation. The blood supply in the optic nerve head has a sectorial distribution, which may explain the segmental vision loss seen in ischemic disorders [13]. The posterior part of the optic nerve is supplied by the pial vascular plexus that is supplied by pial branches originating from the peripapillary choroid, circle of Zinn-Haller, central retinal artery, ophthalmic artery and other orbital arteries. The circle of Zinn- Haller around the optic nerve is complete only in 77% of post-mortem human specimens. The PCA's are end arteries without any anastomoses, allowing for the variations in the location of watershed zones in the optic nerve.

In contrast to the densely supplied anterior and posterior portions of the nerve, the central portion within the optic canal is supplied only by the pial vascular plexus derived from arterial extensions of the anterior and posterior blood supplies and intraneural branches of the central retinal artery. This comparatively sparse vascular supply to the mid portion of the optic nerve renders it most susceptible to ischemia and it is this portion of the nerve that is thought to or related to PION [14]. However, it is important to note that there is significant interindividual variability in the complex blood supply to the optic nerve, especially in terms of the location and pattern of watershed zones [12].

Venous drainage occurs mostly via the central retinal vein that is drained by the internal jugular vein. In the pre-laminar region of the eye, there are retinociliary collaterals to the peripapillary choroidal veins and the drainage through these collaterals can become significant in case of central retinal vein thrombosis [14].

ISCHEMIC OPTIC NEUROPATHY

ION is characterized by decreased blood flow and perfusion pressure to the optic nerve. Postoperative ION is a devastating complication that can occur after a variety of surgical procedures, most often following cardiothoracic surgery [15], instrumented spinal fusion [16, 17], and head and neck surgery [18]. ION can be categorized into anterior or posterior ION, based on whether the insult occurs in the anterior or posterior portion of the optic nerve. The type of ION seen varies depending on the type of surgery performed, with AION occurring most frequently after cardiac surgery and PION occurring most frequently after spine surgery in the prone position or radical neck dissection [9].

Anterior Ischemic Optic Neuropathy

AION is caused by occlusion or hypoperfusion of the anterior optic nerve head by the PCA's and typically presents with sudden onset of painless vision loss and a visual field defect. The funduscopy shows diffuse or segmental disc edema with ensuing atrophy and occasionally splinter hemorrhage's around the optic disc [19, 20]. AION can be classified into arteritic and nonarteritic AION.

Arteritic AION is caused by temporal arteritis and is often seen in the elderly with an elevated erythrocyte sedimentation rate (ESR) and c-reactive protein (CRP), markers that are entirely non-specific in the post-operative period [21]. It is rarely found in the perioperative period.

Nonarteritic AION perioperatively is most often associated with cardiac surgery, especially CABG and generally presents immediately upon awakening from surgery. It occurs both spontaneously in the community and in the perioperative setting, often in patients with pre-existing vascular disease [23]. Although this can occur in healthy patients, risk factors include diabetes mellitus, arterial hypotension, arterial hypertension, blood loss, prone positioning during surgery, prolonged surgery, atherosclerosis, sleep apnea and migraine [13]. The pathophysiology is most likely a combination of these factors, together with abnormal autoregulation and other patient specific characteristics that predispose to ischemic injury

[23]. AION may rarely present as abrupt loss of vision after a delay or period of normal vision lasting hours to days [24].

Posterior Ischemic Optic Neuropathy

PION also manifests as sudden onset of painless loss of vision and visual field deficiencies and results from infarction of the optic nerve posterior to the lamina cribrosa. It is usually discovered on waking from the surgical procedure and tends to present with significant bilateral visual loss or complete blindness [13]. The fundoscopic examination initially reveals a completely normal appearing fundus, with optic nerve pallor and atrophy occurring only after approximately 4-6 wks [24]. In the ASA Registry of spine-related ION, 46% of the patients reported had no light perception [9], which is usually permanent. Similar to AION, POIN can be classified into arteritic and nonarteritic AION. The arteritic form is attributable to temporal arteritis while the nonarteritic form is seen most commonly following spine surgery.

Etiology in the development of postoperative PION include multiple hemodynamic derangements like hypotension, anemia, increased venous pressure, prone positioning during surgery, increased cerebrospinal fluid, and direct ocular compression [25]. Anemia and hypotension are almost always observed in patients that develop postoperative PION [26]. The pial vessels that supply the posterior optic nerve lack an autoregulatory mechanism, rendering them susceptible to ischemia during periods of hypotension and when the blood oxygen carrying capacity is decreased [27]. However, studies comparing patients with POVL after spine surgery with those of controls demonstrated no difference in perioperative hematocrit and blood pressure, suggesting a multifactorial cause [28, 49].

The prone position, a key element to spine surgery, is also the setting in which the majority of postoperative PION is observed. Prone positioning, especially when in the Trendelenburg position, leads to increased orbital venous pressure through an increase in abdominal venous pressure, thus increasing resistance to local blood flow [29]. Direct orbital pressure, often seen with face pillows/cushions or other positioning devices, has also been implicated in the pathogenesis of PION. However, with the resultant decreased perfusion pressure to the optic nerve head and central retinal artery, AION or CRAO would be more likely observed [26]. Avoidance of the prone position and direct ocular pressure is insufficient, however, to prevent postoperative PION, as cases have been documented following surgery in the supine position and with the use of head pins [7, 9, 30].

Pathophysiology of Ion in Prone Position

The theoretical mechanism most often described for ION post spine surgery in prone position is the elevation of venous pressure and development of interstitial edema [11]. Both these processes can cause damage to the optic nerve by compression of the vessels that feed the optic nerve, venous infarction or direct mechanical compression. A rise in central venous pressure can occur in obese patients when their abdomen is compressed during prone position. Similarly venous pressure may be elevated when the head position is lower than the heart, as seen in the Wilson frame. Lower oncotic pressure leading to a growing interstitial

edema can occur when there is significant inflammation and capillary leak such as in situations of major blood loss and/or prolonged cases. The same can occur when less colloid is used overall. All these explanations are simply theories that require further investigation. Why the male sex appears to be a risk factor for ischemic optic neuropathy during prone position is not understood, but it has been suggested that estrogen may serve a protective role [31].

RETINAL ISCHEMIA

Central retinal artery occlusion (CRAO) decreases blood supply to the entire retina, whereas occlusion of a retinal branch (BRAO) affects only a portion of the retina. Both are ophthalmic emergencies and analogous to an acute stroke of the eye. Retinal ischemia has been documented in both adults and children following ocular trauma [32], and also embolic [33] and vasospastic episodes [34].

In spine surgery, these conditions are mostly seen during the perioperative period from improper patient positioning and external compression on the eye [35]. Perioperative trauma was noted in 70% of the cases of CRAO from the ASA Visual Loss Registry, as evidenced by corneal abrasion, ipsilateral decreased supraorbital sensation, ophthalmoplegia, ptosis, or unilateral erythema [9].

Theoretical mechanisms that have been used to explain CRAO include thromboembolism, direct pressure to the globe, and increased intraocular pressure. Decreased oxygen carrying capacity and blood flow to optic nerve such as from hypovolemia, anemia, large blood loss, and peripheral vascular disease, have also been suggested etiologic factors for CRAO. The use of horseshoe-shaped headrest has been associated with this complication. Hollenhurst et al., [3] described CRAO in eight patients after prone spine surgery on horseshoe headrest. Increased risk is also observed in patients with altered facial anatomy, osteogenesis imperfecta, and exophthalmos, all of which can increase effects of external compression [36].

CRAO is often unilateral in presentation with severe visual loss in the affected eye. Pathological features include a cherry-red spot on the macula, a white ground-glass appearance of the retina, attenuated arterioles, and an afferent pupillary defect [37]. Visual loss from CRAO is almost always irreversible and there are no established effective treatment options.

CORTICAL BLINDNESS

Cortical blindness is due to decreased perfusion to the occipital cortex by the posterior cerebral artery. It is caused either by hypoperfusion or embolic phenomenon. Patients with cortical blindness have normal light reflex and fundoscopic examination as the optic tracts and radiations are unaffected. When one side is affected, the patient presents with contralateral homonymous hemianopsia. If both sides suffer ischemic insult, the patient may have peripheral vision loss or complete blindness. Cortical blindness may improve initially after the infarct, but total recovery is rare.

PRES

PRES is a neurologic syndrome that presents as a combination of seizures, visual changes, vomiting, headache, and decreased level of consciousness. It is associated with acute medical illnesses such as hypertensive episodes, autoimmune disease, malignancy, chemotherapy, immunosuppressant therapy, infection, renal disease, vasculitis, eclampsia, and preeclampsia [38]. Although more closely identified with obstetric patients, PRES has also been reported after lumbar fusion [39], hysterectomy [40], and video-assisted-thoracoscopic wedge resection [41]. PRES has characteristic MRI findings. There are two leading theoretical explanations for PRES. One is acute increase in blood pressure above the brain's autoregulatory limit, thereby causing brain edema. The other pathophysiologic explanation is cytotoxic drugs or diseases causing endothelial injury and edema formation. Management is appropriate use of anti-seizure and anti-hypertensive agents and treatment of causative factors. Unlike ION and CRAO, PRES has a favorable recovery pattern.

TREATMENT AND PREVENTION OF POVL

When a patient reports any visual symptoms following surgery, an urgent ophthalmologic consultation should be obtained to determine its cause. If there is no evident ocular injury or central retinal artery occlusion, neuroimaging should be obtained. MRI with gadolinium is preferred to assess for intracranial pathologies, including occipital stroke or pituitary apoplexy [42]. If imaging is negative, the most likely etiology is ION. Patients have been treated with high dose steroids, mannitol or other agents to decrease intraocular pressure, and anti-platelet agents. However, none of these approaches have been shown to be effective [13, 24, 43].

A recent study examined the effect of crystalloid versus colloid and the use of the α -agonist Brimonidine on IOP during prone spine surgery [44]. The study found the mean rate of IOP rise in the prone position and mean IOP at the end of surgery was significantly greater in patients receiving crystalloid than those receiving colloid. Topical Brimonidine also led to a significant reduction in IOP, both intraoperative and postoperative. Ocular perfusion pressure, however, did not vary significantly between the groups as hypotension was aggressively treated, suggesting that maintenance of blood pressure may be a more important factor in determining perfusion pressure. Much larger studies are needed to determine whether maintaining appropriate ocular perfusion pressure reduces the risk of POVL after spine surgery.

Given the poor prognosis and lack of validated treatment options, it is essential to take prophylactic measures during surgery to prevent the development of POVL. The ASA Task Force on Perioperative Blindness, consisting of anesthesiologists, neuro-ophthalmologists, and spine surgeons, suggest periodically checking hemoglobin and hematocrit values, and avoidance of direct pressure on the globe to avoid CRAO injuries. Wide range of devices are available to help limit mechanical ocular compression during prone surgery, but these still require vigilance on the part of the surgeon and anesthesiologist as patient movement and shifting of the device may occur. In high risk patients, additional efforts directed towards

optimizing hemoglobin/hematocrit values, hemodynamic status, and systemic oxygenation may be appropriate [43].

PERIOPERATIVE VISUAL LOSS IN OTHER SURGERIES

Apart from spine and cardiac surgery, perioperative visual loss has also been associated with robotic and laparoscopic surgeries. Cases of visual impairment have been reported to occur in minimally invasive proctocolectomy, laparoscopic nephrectomy and robotic prostatectomy [45-48]. During robotic prostatectomy, increased intraocular pressure occurs due to prolonged duration in steep Trendelenburg position combined with CO₂ insufflation of the abdomen. The central venous pressure within the thorax increases with Trendelenburg position, which may reduce drainage of blood flow from the head, thereby leading to elevation in IOP. During CO₂ insufflation, the increase in intra-abdominal pressure will further augment the increase in intrathoracic pressure. Furthermore, insufflation of CO₂ increases the carbon dioxide in the blood, which can lead to cerebral vasodilatation and increased cerebral blood volume. All these factors ultimately lead to elevation in venous pressure. It is unknown whether the same risk factors for POVL in spine surgery can be applied to laparoscopic and robotic surgeries, but it appears venous congestion and interstitial edema are commonalities among these surgeries.

SUMMARY

POVL after spine surgery is extremely rare, but remains a dreaded complication despite significant efforts to identify risk factors and a pathophysiological mechanism. Potential causes of POVL after spine surgery include anterior ischemic optic neuropathy, posterior ischemic optic neuropathy, cortical blindness, retinal ischemia, and posterior reversible encephalopathy syndrome. The vast majority of cases are related to ischemic optic neuropathy.

Many reports have attempted to link hypotension, anemia, and blood loss to the development of this disease; however, no single mechanism can entirely explain the varied circumstances in which it occurs. This suggests a multifactorial etiology and perhaps individual susceptibility related to varied optic nerve blood supply and anatomy. Postoperative Visual Loss Group, using data from the ASA Post-Operative Visual Loss Registry, identified obesity, male sex, Wilson frame use, longer anesthetic duration, greater estimated blood loss, and decreased percent colloid administration as significant independent risk factors for the development of ION. These risk factors, with the possible exception of male sex, are thought to promote a rise in venous pressure and interstitial edema limiting optic nerve perfusion. Prevention is crucial for limiting the incidence of POVL as there are no treatment modalities once the damage occurs. ASA guidelines listed in the table below are recommended, especially for patients identified as high risk, undergoing procedures that are known to result in visual loss.

Table 1. American Society of Anesthesiologists perioperative visual loss practice advisory consensus conclusions

There is a subset of patients who undergo spine procedures while they are positioned prone and receiving general anesthesia that has an increased risk for the development of POVL. This “high-risk” subset includes patients who are anticipated preoperatively to undergo procedures that are prolonged, have substantial blood loss, or both

Consider continuous blood pressure and central venous pressure monitoring in high-risk patients

Consider informing high-risk patients that there is a small, unpredictable risk of POVL

The use of deliberate hypotensive techniques during spine surgery has not been shown to be associated with the development of POVL

Colloids should be used along with crystalloids to maintain intravascular volume in patients who have substantial blood loss

At this time, there is no apparent transfusion threshold that would eliminate the risk of POVL related to anemia

High-risk patients should be positioned so that their heads are level with or higher than the heart, when possible. In addition, their heads should be maintained in a neutral forward position (without significant neck flexion, extension, lateral flexion, or rotation) when possible

Consideration should be given to the use of staged spine procedures in high-risk patients

Chapter 358

SURGERY FOR INTRAHEPATIC CHOLANGIOCARCINOMA

Kelly Olino, MD and Michael D'Angelica*, MD

Department of Surgery, Hepatopancreatobiliary Service,
Memorial Sloan Kettering Cancer Center, New York, NY, US

ABSTRACT

Surgical resection of intrahepatic cholangiocarcinoma is the only potentially curative treatment option. However, due to the natural history of the disease, most patients present at an advanced stage at which liver resection cannot be considered. As there has been little progress in the development of efficacious chemotherapy and other non-surgical treatments, patients with potentially resectable tumors are generally offered a surgical approach that should include removal of lymph nodes in the gastroduodenal ligament for adequate staging assessment despite no known impact on survival or local recurrence. The aim of this chapter is to present the actual indications for resection, the outcomes after surgery including assessment of prognostic factors and to discuss the role of re-resection, liver transplantation and implant of intraarterial pump for hepatic arterial infusion in unresectable ICC.

KEY POINTS

- The presence of a positive lymph node and multifocal liver disease are the most important prognostic factors effecting survival following surgical resection of intrahepatic cholangiocarcinoma.
- Consideration should be made for removal of lymph nodes in the gastroduodenal ligament for adequate staging assessment despite no known impact on survival or local recurrence.

* Corresponding Author's Email: dangelim@MSKCC.ORG; Fax: (212) 717-3218.

- Complete resection should only be attempted in patients without evidence of multifocal disease or gross lymphatic involvement. Patients with these high risk features should otherwise be considered for treatment with chemotherapy and decisions regarding resection made on a case by case basis.
- Resection of large and locally invasive tumors into biliary and major vascular structures can be undertaken with acceptable morbidity and mortality.
- The goal of any resection for ICC should be that of a margin negative resection.
- The use of liver transplantation should be considered experimental and warrants further investigation.
- The use of hepatic arterial infusion pump therapy has led to promising response rates and survival among unresectable patients compared to historic controls and continues to be the subject of clinical trials.

INTRODUCTION

Intrahepatic cholangiocarcinoma is the second most common type of primary liver tumor. These tumors are thought to arise from the biliary epithelium although there is more recent data supporting the supposition that these tumors may arise from hepatocyte dedifferentiation [1]. Cholangiocarcinoma is commonly classified based upon the location from which it arises. Intrahepatic cholangiocarcinoma arises from second order intrahepatic bile ducts and represents 10% of cholangiocarcinoma with most patients presenting with sporadic disease [2]. There are 3 gross subtypes of intrahepatic cholangiocarcinoma as defined by the Liver Cancer Study Group of Japan including the mass forming, periductal infiltrating and intraductal growth types. The mass forming type is the most frequent subtype representing 60-80% of all cases, with a propensity for intrahepatic metastases and lymph node involvement. The prognosis of the intraductal growth subtype is most favorable and that of the periductal infiltrating subtype is the worst [3].

The incidence and presence of risk factors for the development of intrahepatic cholangiocarcinoma varies widely by country with the highest rates approaching > 80/100,000 in Thailand due to endemic parasitic infection while much rarer in the US (1.67/100,000) and Europe representing less than 3% of malignant tumors [4]. However, numerous reports have indicated that the world-wide incidence is increasing, even in western countries [5]. A recently published analysis using data from the SEER database indicates that since 1983 the incidence of cholangiocarcinoma as well as the utilization of liver directed surgical intervention has increased over time calling for increased attention to this relatively rare disease [6].

PRESENTATION, DIAGNOSTIC WORKUP AND PRE-OPERATIVE STAGING

Patients who present with intrahepatic cholangiocarcinoma are usually asymptomatic at early stages but ultimately develop non-specific symptoms including right upper quadrant or epigastric pain, weight loss or night sweats with advanced stage of disease [7]. Jaundice is

uncommon and only develops in cases where masses are large enough to cause biliary obstruction by mass effect or by direct invasion into the hilum. Given the non-specific nature of presenting symptoms, care should be taken to identify patients who are at risk for developing the disease, particularly in endemic areas. In cases where a liver mass is incidentally found, radiographic imaging in combination with the clinical history makes the diagnosis.

Tri-phasic contrast-enhanced computed tomography imaging typically shows a hypointense liver tumor with ambiguous peripheral borders on non-contrast imaging, but with peripheral enhancement on arterial phase that continues to increase in attenuation during venous phase. It is thought this delay is due to increased stromal fibrosis resulting from the tumor. Findings also commonly include retraction of the liver capsule and distal biliary dilation around the periphery of the tumor [8-10].

CT imaging is also utilized for assessment of extrahepatic disease, satellite lesions within the liver and to determine involvement of vascular and biliary structures in order to determine resectability. Care should be taken to look for evidence of segmental liver atrophy as this is associated with biliary or portal involvement. As with any liver resection, evaluation of both vascular inflow (arterial and portal) and outflow (hepatic vein), as well as an estimation of the residual liver volume should be determined preoperatively. Accurate assessment of the perihepatic regional lymph nodes is limited. Studies typically demonstrate that the incidence of involved nodes is underestimated radiographically with sensitivity ranging from 22-43%, specificity 73-76% and accuracy 62-68%. Risk factors such as tumor size > 5cm and hilar invasion are predictive of having involved lymph nodes [11, 12]. However, even in the case of enlarged lymph nodes (> 1cm), it is difficult to predict metastatic involvement [13]. The conclusions of Grobmyer et al. [14] are frequently cited as evidence of the diagnostic accuracy of preoperative imaging studies in the prediction of involved perihepatic lymph nodes in patients with metastatic or primary liver cancer. Using CT assessment, the negative predictive value was 95% and the positive predictive value was 30%. Truly occult metastatic nodal disease was only found in 1 patient in the study group. However, 75 patients in the study cohort had colorectal metastases, while only 8 patients had intrahepatic cholangiocarcinoma. In fact, most studies addressing the accuracy of imaging in the detection of regional lymph node metastases for cholangiocarcinoma are limited by small case numbers and non-uniform performance of lymphadenectomy.

MRI is complementary to CT and reveals lesions that are usually hypointense on T1 weighted images and hyperintense on T2 weighted imaging with features on dynamic imaging indicative of central fibrosis. The hepatobiliary phase is particularly useful in characterizing the primary tumor and identifying intrahepatic metastases, where these tumors are hypointense and are well delineated. The addition of gadolinium enhanced images can show peripheral enhancement of the mass and provides accurate assessment of vascular involvement. Multi-phase MRI is useful in distinguishing intrahepatic cholangiocarcinoma from hepatocellular carcinoma [15, 16].

Tumor markers such as CA19-9 are not sensitive or specific for the diagnosis of cholangiocarcinoma given the overlap with other hepatobiliary malignancies. However, AFP, CEA, CA19-9 and hepatitis B and C serology should be sent to aid the workup of any patient who presents with a liver mass. AFP is not elevated in cholangiocarcinoma as compared to hepatocellular carcinoma, while CEA and CA19-9 are variably elevated. Markedly elevated CA19-9 >1000 U/ml is a marker for poorer survival [17] and may indicate metastatic disease.

Figure 1. Nomograms for predicting survival following resection of intrahepatic cholangiocarcinoma. Total points are determined by looking at the appropriate value for a given patient variable and assigning points based upon the top axis. Individual points are then summed and a line is drawn down from the Total Points to determine 3- and 5-year survival. (From A) Wang Y. et al. [22] and B) Hyder O. et al. [21]).

Table 1. Clinicopathologic results of selected large retrospective case series for resected intrahepatic cholangiocarcinoma

Author	Year	Center	Patient Number Resected	R0 Resection Rate	Positive LN mets	% Patients with lymphadenectomy	Solitary Tumor	3yrOS	5 yr OS	Negative Prognostic Factors on Multivariate Analysis for Overall Survival
Luo et al. [17]	2014	Shanghai, China	1333	34.8%	28%	41%	64.1%	25.2%	17%	LN metastases, multiple intrahepatic tumors, R1 resection, vascular invasion, Elevated CA19-9 or CEA
De Jong et al. [23]	2011	Multicenter-US, Europe	449	81%	16.5%	55.2%	79%	44.3%	31%	LN metastases, multiple intrahepatic tumors, R1 resection
Farges et al. [19]	2011	Multicenter France	212	76%	40%	100%	41%	43%	28%	pTNM stage, LN metastases, R1 resection
Uenishi et al. [25]	2014	Multicenter Japan	233	100%	37.3%	79%		39.4%	31.1%	Tumor size > 2cm, LN metastases, multiple intrahepatic tumors
Ribero et al. [36]	2012	Multicenter Italy	434	84.6%	36.9%	62.2%	67.5%	47.1%	32.9%	Elevated CA19-9, LN metastases, multiple intrahepatic tumors, (margin not included in analysis)
Marubashi et al. [11]	2014	Osaka, Japan	111	65%	28%	78%	31.4%	41.8%	40.5%	Hilar invasion, multiple intrahepatic tumors, ALT, LN metastases, R1 resection
Uchiyama et al. [24]	2011	Multicenter Japan	341	85%	49.6%	67%	71%	36.4%	29.2%	Elevated CA19-9, multiple intrahepatic tumors, LN metastases, Tumor size > 5cm
Endo et al. [18]	2008	MSKCC	82	85.4%	8.5%	55%	70.7%	NR	NR	LN metastases, multiple intrahepatic tumors, tumor size > 5cm

Since most patients are referred to a surgeon with a liver mass and intrahepatic cholangiocarcinoma occurs less commonly than metastatic disease, workup including upper and lower endoscopy and cross sectional imaging of the chest, abdomen and pelvis is indicated to look for an occult primary tumor. A careful history reviewing any cancer history as well as routine surveillance for gynecologic and breast cancers should be sought. Core needle biopsy has a limited role in the diagnosis of ICC when the tumor is resectable, but is mandatory for patients who are not resectable and are being considered for non-surgical treatment. Histology of biopsy specimens are typically interpreted as adenocarcinoma, while morphology and immunohistochemical analysis can be suggestive of a pancreatobiliary tumor. Biopsy alone, however, is not accurate enough to diagnose intrahepatic cholangiocarcinoma and the above-mentioned workup is mandatory. At our center, we currently use pre-operative biopsy sparingly in cases of patients with resectable disease and instead rely on the clinical scenario and preoperative imaging. In cases where imaging reveals unresectable or multi-focal disease with inconclusive imaging, biopsy is obtained prior to beginning systemic therapy given the difference in treatment between HCC and ICC. Preoperative workup is completed with assessment of liver function and identification of major medical comorbidities that would preclude liver resection.

PATIENT SELECTION/SURGICAL OUTCOMES AND PROGNOSIS

Resection of intrahepatic cholangiocarcinoma is the treatment of choice for non-metastatic disease and is the only treatment associated with long-term survival and cure. Patients who are not amenable to resection have a median survival of 6-9 months with no five year survivors while those undergoing resection have an associated 5-year survival of up to 30% [17-19]. Since patients are asymptomatic at the early stages of the disease, most present with metastatic or locally advanced disease. As there has been little progress in the development of efficacious chemotherapy and other non-surgical treatments, patients with potentially resectable tumors are generally offered a surgical approach.

Recently, multiple case series have identified prognostic clinicopathologic variables that are now recognized to be important determinants to decide who should be considered for operative therapy. Surgeons and oncologists should understand these prognostic factors in order to best select patients who are most likely to benefit from resection. The role of surgery must also be interpreted in the context of the limited impact of systemic chemotherapy on survival [20]. Both recurrence free and overall survival have consistently been demonstrated to be negatively impacted by the presence of lymph node involvement, multifocal intrahepatic disease and the inability to perform a margin negative (R0) resection [11, 17]. The prognostic impact of tumor size and an elevated pre-operative serum CA19-9 on overall survival varies in different series (Table 1). Two recently developed nomograms (Figure 1) also included CEA, CA19-9, vascular invasion, older age and cirrhosis in addition to the clinicopathologic factors noted above in their prediction models [21, 22]. Unfortunately even when these factors are taken into account, a high risk of recurrence and overall poor prognosis exists even among those with the most favorable tumor characteristics.

THE IMPACT OF LYMPH NODE INVOLVEMENT AND THE ROLE FOR LYMPHADENECTOMY

Lymphadenectomy for intrahepatic cholangiocarcinoma is performed more commonly in Asia than in Western centers. Lymph node removal varies from sampling only radiographic or clinically suspicious nodes, to a formal lymphadenectomy based upon nodal drainage patterns. In centers where routine nodal assessment is performed, dissection includes the removal of all fatty tissue and associated nodes in the hepatoduodenal ligament. Some centers include the common hepatic and left gastric artery lymph nodes for left sided liver lesions due to a differing lymphatic drainage pattern for these tumors [26, 27]. Extended lymphadenectomy, although performed much less commonly, includes posterior pancreatic and para-aortic lymph nodes [11, 17, 24, 26, 28].

When lymphadenectomy or nodal sampling is performed, the overall incidence of positive lymph nodes during surgical resection for ICC ranges from 8.5-50% in case series. However, on balance, most series report approximately a 30% lymph node positivity rate [18, 23-25] (Table 1). Retrospective series have reported the importance of positive lymph nodes on patient prognosis and compared this to other important clinicopathologic features such as a positive surgical margins or the presence of multifocal hepatic disease. Luo et al. [17] reported in the subset of patients where a positive lymph node metastasis was found at the time of surgical resection, overall survival was equally poor regardless margin status with 5-year survival reported as 5.3% and 0% respectively. Farges et al. [19] also reported similar findings in their subset of node positive patients with median survival of 18 months in margin positive and 13 months in margin negative patients. De Jong et al. [23], in a multi-institutional western series, reported that a solitary lesion with lymph node metastases fared equally poorly to that of multifocal tumors (Figure 2).

Figure 2. The effect of a positive lymph node on the presence of a solitary versus multifocal disease (From de Jong M. C. et al. [23]).

Although multiple retrospective case series demonstrate the presence of a positive lymph node to be an important prognostic factor correlated with worsened overall survival there are no prospective randomized studies to show an improvement in locoregional control or a survival benefit by performing a lymphadenectomy. It is also controversial whether performing a regional or an extended lymphadenectomy improves staging compared to sampling clinically suspicious lymph nodes.

The evidence supporting lymphadenectomy for appropriate staging is borne from retrospective case series. For example, in the largest case series reported for surgically resected intrahepatic cholangiocarcinoma, Luo et al. [17], reported that 5-year overall survival was lower for patients who were found to have positive lymph nodes on pathology (4.1%) compared to node negative patients (21.7%). The group also reported an association of improved overall survival when involved lymph nodes were limited to the hepatoduodenal ligament as compared to those with involvement of retropancreatic, celiac or para-aortic lymph nodes. On univariate analysis, patients who underwent formal dissection had an improved median survival of 13mo compared to patients who underwent lymph node sampling alone (6mo). Guglielmi et al. [26] analyzed the prognostic significance of performing a lymph node dissection in a subgroup of patients who underwent resection for ICC. The presence of a positive lymph node was again associated with poor outcomes with no five year survivors. As seen in other series [24, 29], the most common site of nodal metastases was in the hepatoduodenal ligament (Table 2). There were no patients in this series that were reported to have distant nodal disease that also did not have synchronous regional nodal disease. This would argue against the need for performing an extended lymph node dissection to ensure adequate staging. The results of the location and incidence of positive lymph nodes and the associated overall survival are shown in Table 3.

Uchiyama et al. [24] examined this further in a retrospective multicenter study in Japan. Patients who underwent an extended lymph node dissection ($n = 228$ out of 341) were compared to patients who underwent resection of the hepatoduodenal lymph nodes or nodal sampling alone. Patients who underwent extended lymph node dissection had a similar 5-year survival of 34.1% versus 32.9% (Figure 3). Loco-regional recurrence rates were not reported.

Figure 3. Overall survival of patients following extended lymphadenectomy beyond the hepatoduodenal ligament for intrahepatic cholangiocarcinoma. (from Uchiyama K et al. [24]).

Guglielmi et al. also analyzed the subgroup of patients who were found to be node negative after lymphadenectomy. Those patients who had > 3 LN removed had a longer median survival than patients who had 1-3 nodes removed (43mo v 18mo). However, Choi et al. [30] reported that the extent of lymph node dissection was not associated with differences in survival in node negative patients with 5-year survival of nearly 40% in both groups. These conflicting findings can be explained by stage migration as those with a smaller number of nodes resected may be harboring occult node positive disease. This is supported by the 60-70% diagnostic accuracy in identifying lymph node involvement based upon preoperative CT imaging in accurately assessing nodal involvement [30]. However, even if these nodes were not detected preoperatively, survival for this disease is dependent upon recurrent disease in the liver and not loco-regional recurrence. In fact, two retrospective studies report that elective lymphadenectomy for solitary clinically node negative tumors suggest that only 4-5% of these patients would derive any benefit [31, 32].

Table 2. Total number of positive and harvested lymph nodes per lymph node station harvested and percentage of patients with positive lymph nodes per station harvested (adapted from Guglielmi A. et al. [26])

Lymph Node Station	Total Number Positive/ Total Number LN Harvested	Percentage of patients with positive LN
Right cardiac region	5/8	1.8%
Left gastric artery	4/25	1.8%
Common hepatic artery	1/25	1.8%
Celiac artery	0/10	0%
Hepatoduodenal ligament	60/247	33.3%
Posterior pancreas head	7/34	7.4%
Superior mesenteric artery	0/6	0%
Paraortic	5/43	5.5%
Total Number	69/398	

Table 3. Characteristics of lymph nodes and associated survival for resected intrahepatic cholangiocarcinoma in patient subgroup who underwent lymphadenectomy (adapted from Guglielmi A. et al. [26])

	N of patients	Median Survival (95%CI)	3-yr survival	5-yr survival	P value
Total LN retrieved					0.56
0	16	32 (13-50)	40	30	
1-3	17	38 (24-51)	56	10	
> 3	37	37 (0-83)	53	42	
LN status					0.05
N0	36	42(21-64)	64	36	
N +	18	19(11-26)	36	0

Positive LN station					0.68
Hepatoduodenal	14	19(0-38)	40	-	
Hepatoduodenal + other	4	12(-)	0	0	

(Note: Median survival in months).

In summary, although the status of regional lymph nodes is an important prognostic factor, performing a regional or extended lymphadenectomy is not associated with a survival advantage. The role of routine regional lymphadenectomy for staging for ICC has not been defined and two recent systematic reviews on the role of lymphadenectomy have failed to help to reach a consensus [28, 33]. Given the limited data, the NCCN currently recommends that a portal (regional) lymphadenectomy is “reasonable” and should be considered during operative intervention and that distant nodal disease should be regarded as a contraindication to surgical resection [34]. In the case of obvious, positive regional nodal disease diagnosed preoperatively, surgical judgment must be exercised to determine whether surgical resection should be undertaken given that a major resection may be truly more palliative than potentially curative.

MULTIFOCAL INTRAHEPATIC METASTASES

The presence of multifocal disease is one of the strongest negative prognostic factors found in multiple case series published in both Western and Eastern experiences (Table 1). Endo et al. [18] reported a median survival of 87 months for those with resected solitary disease versus 19 months in patients with multiple tumors (Figure 4). Two large multicenter, retrospective analyses, one from a Western series and the other from Japan analyzed the prognostic significance of multifocal liver disease [25]. De Jong et al. [23] reported that multifocal disease was associated with poor 5-survival regardless of nodal status (Figure 2). The multicenter analysis by the Study Group for Hepatic Surgery of the Japanese Society of Hepato-Biliary-Pancreatic Surgery reported 5-year overall survival of 49% for solitary liver tumors and 18% for multifocal liver tumors. They also reported that multifocal disease confined to one lobe of the liver had the same overall survival as bilobar disease. Endo et al. [18] reported that the median survival following resection of multifocal hepatic disease in their patient cohort was no different than those patients with liver only disease that were treated non-operatively. Despite the technical feasibility to resect such tumors, such a decision has to be approached with caution given the poor prognosis [25]. These patients are best treated with chemotherapy first. The NCCN guidelines consider multifocal intrahepatic cholangiocarcinoma to be a relative contraindication to resection and only to be considered in highly selected cases [34].

HEPATIC RESECTION AND MARGINS

The goal of any potentially curative operation for ICC is to achieve a margin negative resection even if this requires major vascular or biliary resection with reconstruction [35]. Case series report differences in 5-year survival in those who underwent an R0 or R1 resection of 28.7-50% versus 0-13.9% [11, 17, 18]. However, the impact of margin status on survival dissipates when factors such as the presence of positive lymph nodes, or multiple hepatic lesions are adjusted for on multivariate analyses. When Farges et al. [19] examined the impact of margin status on survival patients with pathologically involved lymph nodes had similar overall median survival with a R1 resection (18mo) or R0 resection (13mo).

However, in the subset of patients with pathologically proven node negative disease and a solitary tumor, a negative margin resection had a 70% survival, with no 5-year survivors in the presence of a positive margin. In node negative patients, on multivariate analysis, a margin width of < 5mm was associated with poorer survival. Of note there were no statistically significant differences between the extent of surgery performed, tumor size or tumor multifocality between groups.

Figure 4. Disease specific survival after resection of intrahepatic cholangiocarcinoma stratified by number of tumors. (From Endo I. et al. [18]).

Ribero et al. [36] evaluated margin status and found a higher local recurrence rate of 74% with positive margins, but 54% of patients with negative margins still recurred locally. The width of that margin did not seem to impact survival or local recurrence. Based upon the reported data, obtaining a negative margin should be the goal for all resections and particular care should be undertaken in patients with solitary, node negative disease.

SIZE

Retrospective reviews have sought to analyze the relative prognostic value of tumor size with varying results (Table 1). The current AJCC 7th edition staging system [37] does not utilize size in determining the T stage as it was not found to be discriminatory in the analysis of the dataset used to formulate staging. However in both versions of the Liver Cancer Study Group of Japan staging system for ICC (LCSGJ) [25, 38], size was included as a discriminatory factor. Patients with a solitary tumor < 2cm in size in node negative patients had over 90% survival compared to 30-40% in tumors $\geq$ 2cm. Despite the exclusion of size in the 7th edition of the AJCC staging, two recently published nomograms (Figure 1), include tumor size as a continuous variable in determining prognosis following resection [21, 22]. Increasing size is associated with worsened pathologic variables such as tumor grade and microscopic vascular invasion [36, 39]. Large tumor size is also a surrogate for other factors impacting outcomes such as the need for major liver resection and R1 resection. Therefore, it

is difficult to determine an exact cutoff value for which tumor size becomes associated with a worse outcome given the variability in reporting other significant clinicopathologic variables. Given limited treatment options for this disease, for solitary tumors, particularly without gross nodal involvement aggressive surgical resection is warranted if an R0 resection can be achieved.

SURGICAL TECHNIQUE: RESECTION AND RECONSTRUCTION

Few studies have looked at the use of diagnostic laparoscopy in ICC. Laparoscopy can prevent a non-therapeutic laparotomy by detecting small volume metastatic peritoneal disease, multi-focal liver disease and even nodal disease. Improvements in cross sectional imaging have decreased the yield of finding metastatic disease at exploration but given the low morbidity of the procedure, this step should be considered to prevent the morbidity of a laparotomy.

Intraoperative ultrasound remains an important study to help guide resection. This can be performed laparoscopically or at the time of laparotomy to look for occult intrahepatic metastases and to confirm intrahepatic anatomy as related to the tumor. Following this, exploration of lymph node basins as described previously should be performed with either nodal sampling of suspicious lymph nodes or formal lymphadenectomy of periportal lymph nodes performed for staging.

Given the large size of tumors at the time of presentation, invasion of the hilum and major vascular structures is not uncommon and require radical resections, not only requiring a major hepatectomy but also vascular and biliary reconstruction. Uchiyama et al. [24] performed a major hepatectomy 76% of cases, with extrahepatic bile duct resection and reconstruction performed in 42.8% and combined vascular and biliary resection in 15.5% of cases. This was accomplished with mortality of 3.2% and morbidity of 34.3%. Ribero et al. [36] in another large multicenter study performed major liver resections in 50% of cases and performed bile duct resections in 55% of cases and major vascular resections in 14.5% of cases. Mortality was 5.3% and surgical morbidity was 35%, with 44% of complications related to the liver. Infectious complications comprised 20% of complications, similar to other published series [39]. Resection should be performed at expert, high volume centers not only to ensure an R0 resection but to safely manage the high rate of post operative complications [11, 35].

SURGICAL MANAGEMENT OF RECURRENT ICC

Recurrence, even amongst those patients who underwent R0 resection with node negative disease is common and usually occurs within the 3 years after surgery. The overall recurrence rate approaches 50% and the sites most commonly involved include the liver, peritoneum, lymph nodes and bone [3, 40]. Endo et al. [18] found that two thirds of patients recurred at a median follow up of 26 months and that over 60% of these recurrences involved the liver. For node negative, solitary tumors the recurrence rate was 47.3% while those with multifocal disease or lymphatic involvement at the time of initial surgery recurred in 92.6% of cases.

Recurrent disease is managed by chemotherapy in combination with other modalities such as radiation, radiofrequency ablation, hepatic arterial embolization and rarely repeat surgical resection. Ercolani et al. [41] reported a case series of 23 patients with recurrent disease. Six patients underwent hepatic re-resection and 8 patients underwent RFA for isolated liver recurrences and were treated concomitantly with chemotherapy. 5-year survival in this highly selected group reached 56%. Hyder et al. [40] reported that following recurrence, 33/161 patients underwent repeated operative intervention. Those that were resected had a median survival of 26 months, while those who received chemotherapy or supportive care alone had a median survival of 9.2 months.

Zhang et al. [42] reported a series of 109 patients with recurrent ICC treated with thermal ablative therapy (n = 77) or repeat hepatic resection (n = 32). Criteria for re-resection were less stringent in this series and included patients with both early and multifocal recurrence within the liver. Patients treated with ablation had a 94.7% rate of technical success but recurrent disease was common with 60% of patients recurring with a median disease free interval of 6.8 months and median overall survival of 21 months. The subgroup of patients who underwent repeat hepatic resection recurred 70% of the time with a mean disease free interval of 9 months and a median overall survival of 20 months. Both groups had 3-year survival approaching 20% with no 5-year survivors from the time of repeat intervention. Multivariate analysis showed that a disease free interval of 1 year or greater and a solitary recurrence were associated with improved overall survival in this cohort. In summary, recurrences are common following resection of ICC and chemotherapy is the backbone for management. We feel that there is a very limited role for repeat surgical intervention and should be only be considered in patients with isolated, solitary recurrences within the liver who have a long initial disease free interval and who do not progress while on chemotherapy.

TRANSPLANTATION

Interest in liver transplantation for ICC was initially proposed for high risk patients, particularly those with large solitary tumors, where removal of the liver would result in a R0 resection, theoretically leading to improvement in disease control and survival. However, outcomes following transplantation for intrahepatic cholangiocarcinoma have been historically poor with 5-year survival rates ranging from 0-42% and 5-year disease free survival rates ranging from 0-30% (Table 4). The same factors associated with poor prognosis following hepatectomy are also seen for liver transplantation including multifocal disease, positive margins and lymph node metastases [43].

Hong et al. [44] reported the UCLA experience of 37 patients who underwent orthotopic liver transplantation for locally advanced (94%) and/or multifocal tumors (60%) that were not amenable to hepatectomy with biliary or vascular reconstruction. Fifty five percent of these patients were cirrhotic, with primary sclerosing cholangitis (67%) and hepatitis (19%) being the most common cause of chronic liver disease. In their retrospective review, the subset of transplanted patients with these very high risk tumors who were treated with both neoadjuvant and adjuvant chemotherapy experienced nearly 60% 5-year compared to those who received adjuvant or no therapy whose survival was 20%. However, treatment with neoadjuvant therapy may not have changed the true outcome, but rather likely allowed for

more specific patient selection. The authors do not indicate what the dropout rate is but as the study reviewed over 20 years of the centers experience, these patients were truly highly selected. Currently, given the scarcity of organs available for donation the International Liver Cancer Association does not recommend transplantation for these high risk patients, while UNOS does not have established guidelines [45].

There are conflicting reports related to outcomes after transplantation for early stage ICC incidentally noted in liver explant specimens from patients transplanted for hepatic cirrhosis or primary sclerosing cholangitis. One case series reported a 50% disease recurrence after a median time of 10months [46]. Another case series reported 3-year overall survival to be 30% with a median survival of 30 months [47]. In contrast to this, a multicenter study from Spain reported 5-year overall survival of 73% for solitary tumors less than 2cm in size [48]. These results are similar to rates expected with partial hepatectomy in patients with normal livers. Currently, known ICC is not an indication for transplantation so although patients with severe cirrhosis with a small, solitary tumor could theoretically benefit from such an intervention, it cannot be recommended at this time.

SURGICAL PLACEMENT AND OUTCOMES OF HEPATIC ARTERIAL INFUSION PUMP THERAPY FOR UNRESECTABLE ICC

The use of hepatic directed intra-arterial therapies including TACE with or without drug-eluting beads and Y-90 radioembolization are discussed in a separate chapter so will not be specifically reviewed here. The Memorial Sloan Kettering Cancer Center is currently studying the use of hepatic arterial infusion chemotherapy with floxuridine and dexamethasone utilizing a surgically implanted pump in combination with systemic chemotherapy. The placement is performed through a limited laparotomy. Typically, a separate subcutaneous pocket for the pump is made laterally in the left lower quadrant of the abdomen. The pump catheter is brought down through the fascia and placed into the lumen of the gastroduodenal artery through a distal arteriotomy and secured with ties. The gastroduodenal artery is the most common site of pump catheter placement and has the best long term durability and complication rate [49]. The right gastric artery as well as all small branches leading to the stomach duodenum and pancreas are ligated and divided off of the GDA and hepatic artery to prevent extrahepatic perfusion. Methylene blue or fluorescein is injected into the pump intraoperatively in order to check liver perfusion.

Two phase II clinical trials [50, 51] totaling 44 patients with unresectable cholangiocarcinoma have been completed and reported thus far. The first trial included 26 patients with unresectable ICC who were treated with regional chemotherapy consisting of FUDR and dexamethasone, 50 while in the second phase II trial, 18 patients were treated with regional FUDR with dexamethasone in combination with systemic bevacizumab. Sixteen percent of patients were previously treated with systemic chemotherapy and over 60% had multifocal disease. Partial response rates for all patients ranged from 53.8% with over 90% experiencing stable disease at a median 2-year follow up. The addition of systemic bevacizumab in the second trial led to unacceptable biliary toxicity leading to the termination of the study. Updated follow up of these trials has shown 23% 3-year and 11% 5-year survival with a median overall survival of 29.3 months. Post trial treatment included systemic

chemotherapy in 95% of these patients and 82% received additional hepatic arterial infusional chemotherapy either alone or in combination with systemic chemotherapy [52]. Three patients were downstaged and underwent complete resection.

Table 4. Overall and disease free following transplantation for intrahepatic cholangiocarcinoma

Author	Year	Site	N	Overall Survival			Author	Year	Site	N
				1-Year	3-year	5-year				
Casavilla	1997	Pittsburgh	20	70	29	18	31	Adjuvant	Yes**	None
Meyer	2000	Cincinnati	207	72	NR	23	51	Adjuvant	Yes	43
Robles	2004	Spain	23	77	65	42	27	Adjuvant	Yes	10
Becker	2007	UNOS	280	74	NR	38	NR	NR	NR	77
Hong	2011	UCLA	38	NR	38	32	41	Neoadjuvant/ Adjuvant	Yes	None

* High risk features include large tumor size, multifocal lesions or positive lymph nodes.

** 9 patients underwent multi-visceral resection to achieve negative margin.

(Adapted from Rana and Hong. Orthotopic liver transplantation in combination with neoadjuvant therapy: A new paradigm in the treatment of unresectable intrahepatic cholangiocarcinoma. *Curr Opin Gastroenterol*, 2012; 28:258-265 and Guglielmi, Ruzzenente and Iacono *Surgical Treatment of Hilar and ICC*, Springer 2008: p. 230).

Table 5. Comparison of hepatic arterial outcomes for unresectable intrahepatic cholangiocarcinoma (modified from Boehm L. M. et al. [53])

Author	Year	Sample	Treatment Regimen	Type of System	Extra-hepatic disease	Multi-focal disease	Median Survival (mo)	Major Toxicity (= > III)
Tanaka et al.	2002	11	5-FU, Doxorubi-cin, MMC, Cisplatin*	Percutaneous Catheter-Port	36%	45%	26 (mean)	18%
Jarnagin et al.	2009	26	FUDR + Dexamethasone	Surgically placed Port	0%	61%	29.5	14.7%
Inaba et al.	2011	25	Gemcitabine	Percutaneous Catheter-Port	36%	NR	11.3	48%
Kemeny et al.	2011	18	FUDR+ Dexamethasone + bevacizumab**	Surgically placed Port	0%	68%	31.1	27%

* multiple different regimens administered.

** systemically administered.

Although not currently defined, patient selection will be equally important when considering those patients with unresectable disease who will derive benefit from treatment with HAI therapy. The regimens used and results of hepatic arterial infusional treatment at other centers [53] (Table 5) is variable with the best results seen by the group at Memorial and by Tanaka et al. [54] despite using different regimens and drug delivery systems. Both groups excluded patients with evidence of extrahepatic disease were excluded and the majority of patients also had solitary tumors. Currently, although promising, the use of HAI therapy is still investigational and continued study will be required to determine its role in treatment.

CONCLUSION

Since surgery remains the only potentially curative therapy complete resection should be attempted in all fit patients with a resectable tumor. The presence of multifocal disease or gross lymphatic involvement should indicate the need for a treatment with chemotherapy with a secondary resection made on a case by case basis. The presence of large and locally invasive tumors into biliary and major vascular structures cannot be considered a contraindication to surgery. The use of liver transplantation is still experimental and warrants further investigation.

Chapter 359

SURGERY FOR HILAR CHOLANGIOCARCINOMA

Daniel Seehofer*, MD, PhD and Peter Neuhaus, MD

Department of General-, Visceral- and Transplantation- Surgery,
Charité - Universitätsmedizin Berlin, Campus Virchow-Klinikum. Berlin, Germany

ABSTRACT

Resection of hilar cholangiocarcinoma is the only potentially curative treatment option. However, to treat with a radical intent this tumor, along with the excision of the bile duct, major or extended liver resections, lymphadenectomy and often vascular resections are needed. Because of the complexity of the procedure, optimal patient selection and preparation, which include in many cases biliary drainage and portal vein embolization, are essential to ensure adequate short and long term results. The present chapter reviews the evidence for the optimal preoperative and intraoperative management of patients with a “Klatskin” tumor.

INTRODUCTION

Complete surgical resection represents the only curative treatment option for patients with hilar cholangiocarcinoma (hCCA). However, liver resection for hCCA is technically demanding and associated with a relatively high postoperative morbidity, compared to other liver resections (e.g. for colorectal metastases). This is based on the following risk factors, which are particularly relevant for patients with hCCA:

- A high loss of functional liver parenchyma, since a small extrahepatic tumor has to be removed with a high amount of functional, non-tumorous liver parenchyma.
- Simultaneous requirement of a complex bilioenteric reconstruction often with multiple, thin-walled intrahepatic second or third order biliary branches.
- Additional vascular resections and reconstructions are often required (mostly portal vein reconstruction).

* Corresponding Author's Email: daniel.seehofer@charite.de.

- Predominance of old aged patients, since the incidence of cholangiocarcinomas is increasing with age.

Therefore, most hCCA are operated in specialized centers, which ensure optimal conditioning of the future liver remnant (FLR) prior to surgery. This might include treatment of cholangitis, relief of cholestasis via ERC or PTC, testing of liver function in combination with volumetric assessment of the FLR and portal venous embolization. These measures help to assure an acceptable perioperative morbidity and a low mortality. However, the long term outcome largely depends on an adequate surgical technique and a selection of the most radical but still sustainable surgical approach for the individual patient. Due to the central location of hCCA with close proximity to paramount vascular structures, the achievable safety margin is generally lower, than in most other GI-Tumors. Hence, the rate of positive margins (R1) is around 20-30%, even in large series of experienced centers.

INDICATIONS AND CONTRAINDICATIONS FOR SURGERY

The two major goals of oncological surgery for hCCA are:

- 1) Curative resection: achievement of negative resection margins (R0 resection).
- 2) Avoidance of severe postoperative complications and especially of postoperative liver failure.

If it is upfront clear, that these two goals cannot be achieved, surgery is contra-indicated. However, in many cases one cannot decide clearly on the basis of preoperative staging investigations including CT, MRI and ERC, if an R0 resection is possible or not. This is caused by the typical growth pattern of hCCA. Radiological definition of the tumor extensions is difficult in the periductal infiltrating subtype, which has the highest prevalence. Tumor extensions of the nodular and the intraductal papillary subtype of hCCA can be better assessed on radiological investigations, however these growth patterns are rare.

For the periductal pattern, on the one hand, tumor extensions might be under-estimated, since tumor progression over the macroscopically visible biliary stenosis is often seen due to an additional periductal growth of the tumor. Therefore a safety margin of 5-10 mm over the visible tumor stenosis should be envisaged, although this often not possible. On the other hand, tumor extensions might also be over-estimated due to a concomitant inflammatory reaction, which is often associated with hCCA. Thus, in many cases the discrimination between R0 or R1 is obtained only intraoperatively by frozen section after severance of the intrahepatic bile duct. At this stage, a point of no return has already been reached. This explains the relatively high rate of R1 resections in the literature. However, there is some indication, that even R1-resection is beneficial for the patient, and 5-year survival rates of up to 20% haven been reported after R1-resection [1].

Therefore, one should progress to surgical exploration, if the tumor is deemed potentially resectable by an experienced hepatobiliary surgeon, obvious contraindications (see below) are absent and the perioperative risk for the patient is acceptable (patient age, liver function, concomitant diseases). Classification systems like the Bismuth type I to IV classification or

the Memorial Sloan Kettering (MSKCC) T1 to T4 stages are useful for the classification of the tumor and the complexity of the surgical procedure. However, in modern times neither Bismuth type IV nor MSKCC T4 generally preclude R0 resection. Accordingly, many recently published surgical series include a high rate of curatively resected Bismuth type IV tumors [e.g. 2].

Form the issues stated above, it becomes clear that contraindications for surgical resection based on local extension of the tumor can only be judged by an experienced hepatobiliary surgeon on the basis of high quality imaging. The same is true for liver function as relative contraindication. Therefore, nowadays all patients with loco-regionally limited hCCA should be discussed in a multidisciplinary tumor board before a final decision concerning resectability or irresectability is made. Potential contraindications for surgical resection of hCCA include:

- peritoneal carcinosis
- distant metastases (lung, liver)
- liver cirrhosis or poor liver function
- infiltration of vascular structures which cannot be reconstructed
- perioperative risk is deemed to high (individual consideration, e.g. due to reduced liver function, complex vascular reconstructions, etc.)

SURGICAL STRATEGY

Rationale for Major Hepatectomy

Hilar cholangiocarcinomas are mostly infiltrating along the biliary tree, in some cases in a discontinuous manner. During planning of the surgical strategy, a biliary safety margin of 5-10 mm should be envisaged if possible. Due to the almost absent muscular layer of the bile ducts, infiltration of the periductal tissue and the adjacent liver parenchyma is seen early and often. Moreover, due to the close vicinity of the biliary confluence to the portal vein bifurcation, occlusion of one main portal branch by tumor infiltration or tumor encasement is seen in around 30% of cases [3]. Based on these tumor characteristics, it can be recognized, that an isolated resection of the extrahepatic bile duct (“hilar resection”) does not meet the requirements of an radical oncological procedure. As a consequence, the risk of tumor recurrence after isolated hilar resection is higher than 90% and long term survival is rarely seen after this procedure [4]. Therefore, limited resections are reserved for very old patients or patients with liver cirrhosis or very poor liver function, who would not tolerate major liver surgery.

To gain an adequate safety margin a simultaneous en bloc resection of the adjacent liver segments without preparation or “lowering” of the hilar plate is inevitable. Moreover, locally more advanced tumors often approximate or even encase vital vascular structures of one or both lobes, which than necessitates (extended) hemihepatectomies. Even if vascular structures are not involved directly, for reasons of oncological radicality extended hepatectomies have evolved as the standard surgical procedure for hCCA - adequate liver function provided.

Accordingly, the rate of simultaneous major liver resection in most recent series is nowadays more than 95 % [5].

Predilection Sites for R1 Resection

The risk for incomplete or marginal tumor resection (R1) resection is highest at the longitudinal tumor extension within the biliary tree. Additionally, at the circumferential margin there are further predilection sites of R1-resection:

- the right hepatic artery, which normally traverses dorsal to the proximal common hepatic duct
- the portal vein bifurcation, which is situated immediately dorsal to the biliary confluence
- the transection margin of the liver parenchyma

As far as possible, these predilection sites for R1-resection should be avoided during surgical preparation. If however, “manifest” R1-resection is diagnosed at the biliary margin by frozen section, an additional resection should be considered, if technically feasible. If than a R0 resection can be achieved, this has been shown to improve the long term prognosis [6].

Planning of the Surgical Strategy: Right vs. Left Hepatectomy

Bilateral surgical exploration of the hepatoduodenal ligament to determine the type of liver resection intra-operatively increases the risk of tumor cell dissemination and therefore opposes the oncological principle of a no touch technique. Thus, it is recommendable to determine the general type of surgical procedure (i.e. right hepatectomy vs. left hepatectomy) early in the diagnostic workup and dissect the hepatoduodenal ligament accordingly (see below). In loco-regionally confined tumors, the surgical strategy is best defined before any invasive measures like ERC or PTC are performed. The ideal basis for the decision making his a high quality MRI with MRCP. Among others, the following information derived from MRI are mandatory for the further treatment strategy:

- the longitudinal tumor extension in the biliary tree (e.g. Bismuth classification)
- potential vascular involvement and/or atrophy of one lobe (e.g. MSKCC classification)
- the volume of the future liver remnant (FLR)

Based on these findings, the subsequent relief of cholestasis and eventual further preconditioning of the FLR can be planned specifically. The principal decision for a right sided or a left sided hepatectomy should be made at this point, however this decision might be demanding at that point and requires some experience with surgery for hCCA.

In about one third of patients, one lobe is severely atrophic (Figure 1), which is also easily seen on MRI. In those cases the atrophic side can be potentially removed, provided the

vascular supply to the contralateral lobe is free of tumor invasion (or the vascular supply can be reconstructed during surgery) and the contralateral biliary infiltration allows reasonable biliary reconstruction. This commonly requires at least tumor free second or third order biliary branches. However, especially after left hemihepatectomy the reconstruction of 4 to 8 orifices is often required due to the early branching of the right biliary tree.

If none of the lobes is atrophic, and the local tumor extension permits a right sided hepatectomy, this procedure is thought to be the most radical approach for hilar cholangiocarcinoma for several reasons:

- An adequate biliary safety margin is achieved more likely on the left side, since the left hepatic duct has a common course of 1 to 5 cm before ramification to the segmental ducts, whereas the right hepatic duct has only a short common course of 1 cm or less. By using a right trisectionectomy the biliary system can be divided in the umbilical fissure, which allows curative tumor resection in a high percentage of cases [7].
- The right hepatic artery has not to be separated from the bile duct (danger of tumor cell dissemination) and can be dissected only at its origin, distant from the tumor region. In contrast the left hepatic artery commonly runs away from the tumor region on the left margin of the hepatoduodenal ligament (Figure 2)
- The portal vein bifurcation can be resected en-bloc with the tumor region, which further increases the circumferential safety margin. The anastomosis of the main portal trunk to the left portal vein with its long common course is generally easier than to the right portal vein, due to the branching pattern of the right portal vein.

Figure 1. Severe atrophy of the left liver lobe due to occlusion of the left portal branch.

Figure 2. View of the hepatoduodenal ligament with the left hepatic artery (LHA) at its left border. The dotted line represents the dissection line during hilar en bloc resection for extended right hepatectomy. The dissection line proceeds at the upper duodenal border and along the LHA.

Figure 3. Future liver remnant (FLR) after right trisectionectomy (green), which constitutes about 25% of the total liver volume. To increase the FLR, partial preservation of segment 4 may be considered (red area).

The major drawback of extended right hepatectomies or right trisectionectomies for hCCA is the extensive loss of functional liver volume (Figure 3). This results in a relatively small future liver remnant. Therefore, this technique should be used cautiously in patients with markedly impaired liver function and in old-aged patients with a presumed reduced liver regeneration capacity. If permitted by the local tumor extensions, left hepatectomy might be the safer alternative for high risk patients (old aged, poor liver function). In contrast, for

young and fit patients extended right hepatectomies might increase the oncological radicality and improve the long term results [8].

Preconditioning of the Future Liver Remnant

Since both, right and left hepatectomies for hCCA represent high risk surgical procedures, an optimal preconditioning of the future liver remnant (FLR) is essential to reduce the postoperative morbidity. This includes:

- **Relief of cholestasis** by preoperative biliary drainage of the FLR (the contralateral side might be left un-drained) either internally (ERC) or percutaneously (PTC). Surgery is mostly performed after decrease of serum bilirubin to normal or close to normal.
- **Treatment of cholangitis** by biliary drainage and antibiotics (if present in the hemi-liver to be resected, biliary drainage of both sides is necessary)
- **Portal vein Embolization** of the right portal branch is recommendable prior to extended right hepatectomies, especially in older patients, in case of impaired liver function or if volumetry reveals a small FLR. Also before left trisectionectomies portal vein embolization of the left lobe is occasionally used, subject to the relative size of the FLR. In general, surgery is performed 2 to 6 weeks after embolization and consecutive hypertrophy of the FLR.

SURGERY

Surgery for hCCA starts with a uni- or bilateral transverse plus median upper abdominal laparotomy. Although laparoscopic or hybrid approaches to hCCA have been described [9], open surgery remains the standard of care. Initial staging laparoscopy might be considered, if there is a suspicion of peritoneal carcinosis or diffuse bilateral liver metastases, which is both relatively seldom in early stages of hCCA. Apart from that, in most cases no additional information about local tumor extension or operability is provided by laparoscopy [10]. Moreover, if required the parenchymal quality of the liver can be evaluated by laparoscopy and biopsy.

After laparotomy the abdomen is explored for conditions precluding curative tumor resection like peritoneal seeding, distant metastases, and lymph node metastases in the para-aortal region. Peritoneal implants are most often seen in the subphrenic and subhepatic region, but also in all other predilection sites of the abdominal cavity. Thereafter the local tumor extensions are roughly evaluated by palpating the intrahepatic bile duct in the region of planned division. For right sided hepatectomies, this is the region around the umbilical fissure, which can be palpated after dissection of parenchymal bridge between the segments 2 and 4. Palpation is more difficult during left sided hepatectomies at this stage, since especially the cranial parts of the tumor (right posterior sectoral duct) are difficult to palpate before further preparation of the right sided vascular structures and dissection of the liver parenchyma.

Hilar Preparation and Lymphadenectomy

The surgery commonly starts with the preparation of the hepatoduodenal ligament. Thereby it is envisaged to dissect as far as possible from the tumor region. In general the supplying vascular structures (portal vein, artery) to the FLR are freed of all lymphatic tissue. The preservable vessels are dissected until the region proximal to the tumor. If they are not infiltrated, tumor resection is possible and further lymph node dissection proceeds. A Kocher maneuver can be helpful for retropancreatic lymph node dissection (status after completed lymph node dissection for left hemihepatectomy is shown in Figure 4). The standard lymphadenectomy of hCCA includes:

- all lymph nodes of the hepatoduodenal ligament
- retropancreatic lymph nodes
- lymph nodes along the common hepatic artery
- eventually coeliac lymph nodes

Special Aspects of Right Hemihepatectomy

For extended right hemihepatectomy en bloc with extrahepatic bile duct resection and resection of the portal vein bifurcation (“hilar en bloc resection”) the complete hilar dissection proceeds distant to the tumor region (Figure 2). Surgical preparation is performed only on the left side of the hepatoduodenal ligament and distally close to the duodenum. Thereby the tumor region is spared out in order to comply with the onco-surgical principle of a no-touch technique.

Figure 4. Status after left hemihepatectomy with lymph node dissection. All lymph regional nodes have been removed and the right hepatic artery (RHA) until the common hepatic artery (AHC) and the coeliac trunc (CTr) have been completely freed from the lymphatic tissue.

Figure 5. Situs after hilar preparation for right trisectionectomy after portal vein anastomosis of the main portal trunk (PV) with the left portal vein (LPV). The left hepatic artery (LHA) has been completely skeletonized. The whole preparation proceeded distant to the tumor region (Tu).

In brief, the left hepatic artery is skeletonised up to the umbilical fissure. The right hepatic artery is prepared and divided solely close to its origin. The further course behind the common bile duct is left untouched. The left portal branch is encircled in the umbilical fissure, the main trunk of the portal vein is encircled above the pancreas. The common bile duct is divided distally in a region which seems tumor free by palpation (frozen section). Spillage of bile is to be avoided, since it may contain tumor cells. Next, an end-to-end anastomosis of the main portal trunk and the left portal branch is performed (Figure 5). Thereby the portal vein bifurcation remains undissected at the tumor region. The hilar preparation is now finished. The right liver lobe and the caudate lobe are completely mobilized from the inferior caval vein by division of the short hepatic veins and the right hepatic vein. Afterwards the liver parenchyma is transected along the falciform ligament (right trisectionectomy, Figure 6) or parts of segment 4 may be preserved if permitted by the local tumor extensions (Figure 3). Finally the left hepatic duct is divided intrahepatically after completion of the the parenchymal dissection and again the margin is sent for frozen section

Special Aspects of Left Hemihepatectomy

In contrast to the extended right hemihepatectomy with hilar en bloc resection, preparation of the right hepatic artery behind the common bile duct is mandatory for left hemihepatectomy. Afterwards the main portal trunk is dissected as well as the right portal branch. The left hepatic artery and the left portal vein are divided centrally. The common bile duct is divided distally above the duodenum. The left lobe and the caudate lobe are separated from the caval vein. Afterwards the parenchyma is transected and finally the right hepatic duct is divided in the parenchyma. Commonly, two or more bile duct orifices have to be reconstructed after left or extended left hemihepatectomy (Figure 7).

Figure 6. Situs after completion of right trisectionectomy with portal vein anastomosis and regional lymph node dissection.

In case of tumor infiltration of the portal vein bifurcation the portal vein is now clamped above the pancreas and at the right portal branch using vascular clamps. Both vessels are divided and reconstructed end to end.

Vascular Resection

Portal vein resection and reconstruction - either in case of infiltration or to increase the oncological radicality ("hilar en bloc resection", [7]) can be regarded as a standard procedure nowadays, since no significantly increased complication rate is observed. The portal vein is reconstructed by direct suture (Figure 5 and Figure 6) in the majority of cases. Only occasionally, an interposition graft is necessary.

Figure 7. Creation of a bilioenteric anastomosis with the sectoral branches to the anterior (S 5/8) and the posterior (S 6/7) segments using the parachute technique after left hemihepatectomy.

In contrast, arterial reconstruction is associated with an increased complication rate [11]. However, it might be considered in case of arterial infiltration in selected cases, mainly in younger patients and in lymph node negative cases. Different methods of arterial reconstruction have been described. Depending on the length of the defect, reconstruction is possible either by direct suture, by transposition of another artery or by a vascular interposition graft [9].

Multivisceral Resection

If the distal bile duct margin is infiltrated by tumor cells (R1) in the frozen section investigation, a radical additional resection would require a resection of the pancreatic head in most cases. This might be considered in patients with an acceptable general risk for such an extended procedure, if the oncological risk is also moderate (e.g. negative lymph nodes or low lymph-node ratio). Adequate patient selection provided, promising long term results have been reported, e.g. by Ebata et al., who observed a 5 Year survival of 37% after en bloc hepatectomy and partial pancreatoduodenectomy [12].

Biliary Reconstruction

Biliary reconstruction can be technically demanding after liver resection for hCCA, since in many cases more than one orifice has to be reconstructed. Moreover, especially after left hepatectomies, in many cases segmental bile ducts have to be sutured, which occasionally can be very fragile and thin walled. Especially, if several orifices have to be reconstructed, it is important not to overlook an orifice. If possible, orifices which are situated in close proximity are unified by sutures. For bilioenteric anastomosis a Roux-en-Y jejunal limb is prepared and placed next to the biliary orifices e.g. via the retrocolic route in a tension free fashion. Bilio-enteric anastomosis is performed by interrupted (Figure 7) or running suture. Many centers routinely place biliary drains, e.g. transhepatic drains to reduce the risk of anastomotic leakage.

POSTOPERATIVE COMPLICATIONS

Surgery for hCCA is technically demanding and the relevant loss of functional liver parenchyma is combined with a vulnerable bilioenteric anastomosis. Therefore, even in experienced centres, postoperative complications are to be expected in around every third patient and the in hospital mortality is about 5 to 8 %.

The commonest complications are insufficiencies of the bilioenteric anastomosis, bile leaks from the cut surface, infectious complications (mainly cholangitis), vascular complications (especially after vascular reconstructions) and hepatic failure. The latter is often triggered by one other, of the aforementioned complications. Known risk factors for postoperatively elevated bilirubin levels as one indicator of liver failure include preoperative total bilirubin values of more than 2 mg/dl, postoperative major complications and extended

hepatectomies [13]. Namely major postoperative complications, and especially severe infections, are thought to influence postoperative hepatic regeneration and liver function. Likewise a correlation between postoperative hepatic dysfunction and postoperative infectious complications has been described, especially in patients with a small residual liver volume of less than 27 % [14]. Vascular complications are the second major complication as cause of postoperative hepatic failure [15]. However, using modern peri-operative measures including optimal preconditioning of the FLR, the mortality is decreasing and therefore aggressive resection for hilar cholangiocarcinoma is justified despite the relatively high morbidity.

LONG TERM RESULTS

Disease recurrence is the commonest cause of death after resection of hCCA. Predilection sites of tumor recurrence include the peritoneum, the liver remant and the paraaortal lymph nodes. The 5-year overall survival rate of recent single center experiences, ranges between 20% and 40% ([16-23], Table 1). Beneath the depth of tumor invasion (T-category), also the macroscopic tumor type (papillary vs. diffuse infiltrating), vascular invasion and positive lymph node status are known major determinants of long term outcome.

In retrospective analyses, several other factors were found to be significantly associated with impaired long term survival. These include poor differentiation of the tumor (G3), irresectability, incomplete tumor resection (R1, R2) and distant metastases. The latter three factors are normally associated with a 5 year survival of 0%. However, after R1 resection long term survival seems to be achievable in a minority of patients. Whereas 5 year survival after R1 resection is 0% in several publications, others have observed a 5 year survival of 10 to 20% (Table 1).

Table 1. Long term results in exemplary large single center experiences within the recent years

CONCLUSION

Resection for hCCA is one of the most technically demanding procedures with high postoperative mortality rates of 5 to 8 %. Therefore, a precise preoperative staging, accurate patient selection and the optimization of the FLR that might include biliary drainage and portal vein embolization, are the key factors for a successful hepatectomy. Management in highly specialized centers is the only way to ensure the optimal conditioning to obtain the best outcomes

SUMMARY

- Resection of hilar cholangiocarcinoma is a demanding procedure associated with substantial morbidity and mortality rates of 5-8%.
- Accurate staging and proper patients selection that must include testing of liver function in combination with volumetric assessment of the FLR, are essential step before surgery.
- Preoperative optimization of the liver with treatment of cholangitis, relief of cholestasis, and portal venous embolization in patients with an inadequate FLR volume might assure acceptable outcomes.
- An aggressive surgical approach is essential to reduce the rate of the rate of positive margins (R1) resection which is still around 20-30%.

Chapter 360

SURGERY FOR DISTAL CHOLANGIOCARCINOMA

ABSTRACT

The occurrence of a distal cholangiocarcinomas is extremely uncommon.

However, due to early signs and symptoms, it can be diagnosed once surgical resection can still be achieved. The patients often present with a pancreatic head mass and obstructive jaundice. Rather than obtaining a preoperative histological diagnosis, clinicians should focus on cancer staging, assessment of “resectability” and the need to palliate the bile duct obstruction.

Pylorus-preserving pancreaticoduodenectomy (PPPD) represents the surgical procedure of choice in case of distal bile duct cancer. To achieve a “R0” resection, associated with proper lymphadenectomy, plays a key role in reaching long term survival. In particular lymphadenectomy serves as a staging procedure, and at least 11 lymph nodes must be collected during surgery.

With the improvement of standard of care and with the introduction of dedicated clinical pathways, patients undergoing major pancreatic resections for distal bile duct cancer (DBDC) can be managed following fast-track protocols, in order to reduce both surgical morbidity and the length of hospital stay. PPPD for DBDC is burdened by the same complication pattern of surgery for pancreatic ductal adenocarcinoma. However due to the low incidence of obstructive pancreatitis and consequent harder gland texture, post-operative pancreatic fistula (POPF) rate is higher.

Prognosis in case of DBDC is still poor, but an R0 PPPD performed at high volume center, allowing for an acceptable rate of morbidity and mortality, represents the best chance for cure.

INTRODUCTION

Malignant neoplasms of the bile duct are relatively rare with an annual incidence rate in Western countries of 1-2 cases per 100,000 [1]. Incidence of bile duct cancer is related with ageing. It is a slow growing tumor, so that patients and physicians can be unaware of its presence. With growth, infiltration of adjacent vessels can occur and often the primary tumour becomes unresectable.

Cholangiocarcinomas are classified in intrahepatic, perihilar and distal (table 1).

Among them, DBDC is the second most frequent [2] and its prognosis is comparable to those of other two types [3-5]. When cancer arises in the distal part of the main bile duct it usually causes symptoms including early jaundice and cholangitis. This chance can lead to early diagnosis and surgically excision.

Table 1.

Classification of cholangiocarcinomas and relative distribution in Western countries [adapted from [6]]	
Intrahepatic	8%
Perihilar	50%
Distal bile duct	42%

PREOPERATIVE ASSESSMENT

To obtain a preoperative histological diagnosis of DBDC is not possible all cases, so that this is only presumed in several cases. The incidence of cholangiocarcinoma is often overestimated on the basis of preoperative clinical and radiological evaluation. In our series, on 74 cases (unpublished data) of highly suspected cholangiocarcinoma 39 cases (52,7%) resulted to be pancreatic ductal adenocarcinoma. On the contrary, only 9 cases (16,9%) of 53 histologically proven cholangiocarcinoma were interpreted with an alternative diagnosis (mostly pancreatic adenocarcinoma).

There is no evidence that a patient with a resectable pancreatic head mass should undergo histologic assessment of the diagnosis through a fine needle aspiration (FNA; US, CT scan or EUS guided) or biopsy. On the other hand, histologic confirmation is the first fundamental step in case of both unresectable and borderline resectable masses, since neoadjuvant chemotherapy should be at least considered.

Our Institutional diagnostic work-up for periampullary region masses generally includes clinical examination, laboratory tests with oncologic markers (i.e. serum levels of Ca19.9 and CEA) and abdominal contrast-enhanced CT-scan. We consider a lesion as resectable when it is confined to the distal bile duct, even in the presence of invasion of pancreas or duodenum, without evidence of metastatic disease to the liver, lungs, peritoneum, or any other distant site. Direct invasion of adjacent organs such as stomach or colon, as well as gross lymphadenopathy, may suggest the simultaneous presence of distant spread. When tumour extents to celiac trunk (very rare for distal cholangiocarcinomas), common hepatic artery, and superior mesenteric artery it can be classified as locally advanced. At our Institution, the

presence of an abutment of more than 180° and no longer than 2 cm in length of superior mesenteric vein or portal vein-superior mesenteric vein confluence also precludes surgical resection. Venous vascular resections can be carried out in order to obtain an R0 resection, however survival benefits represents still a matter of debate [7, 8].

Contrast-enhanced ultrasound (CEUS) may add some important information about locoregional spread of the disease through the dynamic evaluation of perfusion of perampullary region with a high accuracy in detecting vascular infiltration or encasement. CEUS can better define liver involvement in case of metastatic disease [9-11].

Magnetic Resonance with Cholangio Pancreatography (MRCP) is advocated to better define the presence of bile duct stenosis (such as for pancreatic head mass, cholangiocarcinoma, choledocolithiasis) [12-15]. This is particularly useful once CT-scan fails to show a mass growing in the perampullary region. Additional information can be retrieved by the use of Endoscopic Retrograde Cholangiopancreatography (ERCP), the procedure of choice to palliate obstructive jaundice. ERCP can be useful to perform fine-needle aspiration (FNA), transpapillary biopsy and brush cytology. Unfortunately, these sampling methods are poorly sensitive (30-70%) even if highly specific (90%) [14, 16-18].

Endoscopic ultrasound (EUS) findings (i.e. thickness of biliary wall, polipoid or non-polipoid cancer protrusion into the biliary lumen) in order to distinguish the nature and the site of distal bile duct obstructions and to evaluate the extent of the disease (i.e. nodal involvement) [19].

SURGERY

The treatment of choice for DBDC is represented by surgical resection. The reported resectability rates range between 22% and 89% [20]. Radical resection can only be achieved through pancreaticoduodenectomy (either pylorus-preserving or Kausch-Whipple procedure). Both procedures provide a comparable outcome for distal cholangiocarcinoma [21-24]. A meta-analysis demonstrated that the Kausch-Whipple procedure and the pylorus preserving procedure reach equal results in terms of perioperative morbidity and mortality [25]. PPPD can be considered as a safe procedure in high-volume centers, but still burdened by an overall 30% morbidity risk and a mortality rate of around 3% (26-28). In a series reported in literature including 11.559 pancreatic procedures, the Pancreatic Surgery Mortality Group reported an overall 30- and 90-day mortalities of 0.96% and 1.89%, respectively [26]. The vast majority of complications were referable to issues related to pancreatic anastomosis. At our Institution, we prefer to perform pylorus-preserving pancreaticoduodenectomy, with a non-stented end-to-side pancreaticojejunostomy.

Technique

At our institution, we historically prefer a xifo-umbilical incision. After a meticulous exploration of the abdominal cavity, to detect small metastases unrevealed by preoperative instrumental tools, a Kocher maneuver is then performed in order to palpate pancreatic head and to assess if eventually the tumor spread already involved the superior mesenteric vessels

(artery and vein). At this point intraoperative ultrasound could be useful to deeply investigate the cranial extension of the neoplasm along the bile tree, to deepen hepatic suspect nodules and to clarify doubtful vascular adhesions. If neither macroscopic, nor instrumental nor haptic signs of unresectability are identified, then we proceed with a pylorus-preserving pancreaticoduodenectomy (PP-PD) [29].

The noteworthy difference between the surgical strategy of a PP-PD (or PD) for a pancreatic cancer or for a biliary cancer is represented by the necessity to do first the frozen-section of the biliary duct stump. It is important to take into account the pattern of anatomic spread of cholangiocarcinoma.

Akamatsu et al. argued that it is possible to distinguish two types of spread: longitudinal spread and vertical spread [30]. The first aspect refers to the main feature of extrahepatic cholangiocarcinomas, that is the mucosal and submucosal infiltration trend, according to the tumor's growth pattern [31]. The latter concept, on the contrary, refers to direct involvement of the surrounding duodenum or pancreas, or hepatoduodenal ligament (distant metastases, including those to para-aortic lymph nodes it is considered as an extension of this idea).

Therefore, in a curative radical intent to remove all the possible invasive carcinoma cells spread within the biliary wall, a 20-mm margin beyond the macroscopically palpable one is required [31].

If the margin is positive then additional segmental resection of the hepatic duct is required to obtain a R0 procedure. It is important to note that, for distal cholangiocarcinomas arising from the cranial portion of the intrapancreatic bile duct, in case of superficial spread of the carcinoma along the bile duct (i.e. in a short biliary tree) toward the biliary hilum, then it is mandatory to perform a major hepatectomy (extended right- or left- hemihepatectomy) with pancreaticoduodenectomy to obtain R0 resection [32]. We routinely perform also frozen-section of the pancreatic resection margin and, obviously, cholecystectomy. End-to-side hepatico-jejunal anastomosis is our selected option for reconstruction of biliointestinal continuity, usually 15-20 cm distal to pancreatico-jejunostomy (or in the isolated loop in case of pancreatico-gastrostomy), with 3-0, 4-0 or 5-0 interrupted sutures according to the surgeon. Occasionally, we perform two half-continuous sutures when the diameter of common hepatic duct is greater than 1 cm.

Restoration of pancreatico-intestinal continuity is still a big challenge for pancreatobiliary surgeons.

Several studies have made huge efforts in order to solve this long-standing problem. However, none of them seems to be the cornerstone of the management of pancreatic anastomosis [33-35]. A recent multicenter randomized study stated that pancreatico-gastrostomy should be the preferred pancreaticoenterostomy, independently of pancreatic duct size and without the use of pancreatic stent [36]. Nevertheless, this study also contains several limitations that do not make us able to adopt this option as the definitive one [37].

At our Institution, pancreatico-jejunal anastomosis is the preferred option for pancreatic reconstruction. However, in selected cases (i.e. soft pancreatic tissue, small main pancreatic duct size) we adopt the reconstruction with pancreatico-gastrostomy [figure 1].

As reported in the literature, bile duct resection alone cannot reach the appropriate lymph nodes collection and should be reserved for highly selected cases because only few patients obtain curative resection margins at the final pathology [30, 38, 39].

Figure 1. Open pancreaticogastrostomy technique [from [29]]. Legend: through a posterior gastrotomy the pancreatic stump is invaginated for 3-4 cm into the stomach, through an anterior gastrotomy a pancreaticogastrostomy is then performed.

Station	Name
1	Right cardial lymph nodes
2	Left cardial lymph nodes
3	Lymph nodes along the lesser curvature of the stomach
4	Lymph nodes along the greater curvature of the stomach
5	Suprapyloric lymph nodes
6	Infrapyloric lymph nodes
7	Lymph nodes along the left gastric artery
8a	Lymph nodes in the anterosuperior group along the common hepatic artery
8p	Lymph nodes in the posterior group along the common hepatic artery
9	Lymph nodes around the celiac artery
10	Lymph nodes at the splenic hilum
11p	Lymph nodes along the proximal splenic artery
11d	Lymph nodes along the distal splenic artery
12a	Lymph nodes along the hepatic artery
12p	Lymph nodes along the portal vein
12b	Lymph nodes along the bile duct
13a	Lymph nodes on the posterior aspect of the superior portion of the head of the pancreas
13b	Lymph nodes on the posterior aspect of the inferior portion of the head of the pancreas
14p	Lymph nodes on the proximal superior mesenteric artery
14d	Lymph nodes along the distal superior mesenteric artery
15	Lymph nodes along the middle colic artery
16	Lymph nodes around the abdominal aorta
16a1	Lymph nodes around the aortic hiatus of the diaphragm
16a2	Lymph nodes around the abdominal aorta (from the superior margin of the celiac trunk to the inferior margin of the left renal vein)
16b1	Lymph nodes around the abdominal aorta (from the inferior margin of the left renal vein to the superior margin of the inferior mesenteric artery)
16b2	Lymph nodes around the abdominal aorta (from the superior margin of the inferior mesenteric artery to the aortic bifurcation)
17a	Lymph nodes on the anterior surface of the superior portion of the head of the pancreas
17b	Lymph nodes on the anterior surface of the inferior portion of the head of the pancreas
18	Lymph nodes along the inferior margin of pancreas

Figure 2. Lymph Node Stations according to JPS [40].

Lymphadenectomy

We want to underline the importance of regional lymphadenectomy. Using the pancreatic cancer metastatic spread as a model, according to Japanese Pancreas Society (JPS) eighteen lymph-node stations can be defined. Consequently, 3 levels of nodal involvement can be identified according to lymphatic spread of pancreaticobiliary malignancies (figures 2-3; table 2).

It has been reported that the frequency of lymph node metastases in distal cholangiocarcinoma ranges between 22% and 58%, while the absence of lymph node metastases represents a predictor of outcome [41]. The 7th edition of AJCC recommendations suggested that at least 3 lymph nodes should be examined for accurate staging of extrahepatic cholangiocarcinomas. The rationale for this statement is unclear, in fact recent studies has identified that node negative (N0) patients with a total lymph nodes count greater than 11 show a better prognosis that N0 patients with lesser than 11 lymph nodes yielded [39]. Therefore, we can state that it is important to harvest at least 11 lymph nodes in order to avoid patients' understaging.

Figure 3. Schematic anatomic location of lymph-node stations (from Japan Pancreas Society - General rules for the study of pancreatic cancer - 5th Ed. Tokyo Kanehara 2002).

Table 2. JPS Lymph node group classification (adapted from [40])

Group 1 Lymph node stations	13a*, 13b*, 17a*, 17b*
Group 2 Lymph node stations	6*, 8a*, 8p*, 12a*, 12b*, 12p*, 14p*, 14d*
Group 3 Lymph Node stations	1, 2, 3, 4, 5, 7, 9*, 10, 11p*, 11d, 15, 16a2, 16b1, 18*

* Regional lymph nodes by the UICC.

Recently, as for pancreatic cancer, it has been reported that the ratio between the number of metastatic lymph nodes and the total number of harvested (Lymph Node Ratio, LNR) is an independent predictor of survival for patients with distal cholangiocarcinoma, being > 0.2 (or 20%) associated with a poorer prognosis [41].

Moreover, there is knowledge that an extended lymphadenectomy including para-aortic lymph nodes dissection has a mere staging role rather than a curative in pancreaticobiliary tumours. As for pancreatic cancer [42] the disease specific survival for patients with positive para-aortic lymph nodes, in fact, is similar to metastatic patients. This data suggest that survival is not influenced by an extended lymphadenectomy [43-45]. Instead, clinical and prognostic significance of nodal micrometastases in biliary cancer it is still unclear [46-48].

Vascular Resection

Advances in perioperative care and rising interest in long-term survival have led to an expansion of the resectability criteria for pancreaticobiliary tumors. Hence, the debate on vascular resections during pancreaticoduodenectomy has risen. However, this subject has always been described with controversial results in terms of survival, morbidity and mortality. The rationale for a vascular resection is to achieve the R0. Unfortunately the vast majority of original studies focused on vascular resection lack of a rigorous assessment of the R status. As for venous resections, a recent systematic review showed the results coming from 28 retrospective studies, all focused on resection of superior mesenteric-portal vein. The reported mortality rates ranged between 0% and 17%, the median rate of bleeding was 4%, the rate of vascular thrombosis was 0% and the reoperation rate was 9% [7]. The Authors did not find any correlation between microscopic neoplastic vascular infiltration and overall survival. Interestingly they anyway propose to change the surgical approach suggesting an end-to-end or graft reconstruction once a venous infiltration is present [7].

As for the arterial infiltration, a recent systematic review and meta-analysis took into account 26 studies. Perioperative morbidity rates of arterial resection associated to pancreatic resection ranged between 16.7% and 100%, reoperation rates ranged from 0% to 75%, median mortality rate was 11.8% and no benefits were reported in terms of survival. Hence, arterial resection should be avoided in every cases [8].

Our recommendation is to avoid R2 resections, while venous resection should be carried out only in case of macroscopic vascular infiltration of less than 180° and for less than 2 cm in length, in order to obtain an R0. Arterial resections should always be avoided.

Palliation

A relevant amount of patients affected by DBDC cannot be candidate for radical surgery. Since jaundice is the most common presenting symptom, endoscopic palliative procedures play an important role in patients suffering from DBDC [49], in order to improve patients' quality of life and to reduce the possible side effects due to the toxicity of bilirubin. If the patient it is not candidate for radical resection because of a locally advanced disease, the stenting of common bile duct should be carried out before neoadjuvant therapy. In particular, metallic stents should be preferred as for metastatic patients. Once the ERCP approach is not

capable to solve jaundice, it is preferable to proceed with percutaneous transhepatic biliary drainage (PTBD), possibly with metal self-expanding stent, because they have shown to be associated with more patency and less risk of obstruction than plastic ones [50]. Surgical bypass with hepaticojejunostomy or choledochojejunostomy should be considered as the last step only once less invasive techniques have eventually failed.

POSTOPERATIVE CARE

Postoperative management varies across Institutions and is greatly influenced by several economical and social aspects. According to the recent progress obtained in the field of enhanced recovery after surgery, a lot of validated fast-track protocols have been introduced also in the field of pancreaticobiliary procedures, with a consequent reduction in the length of hospital stay and the costs. It is still a matter of debate whether fast-track protocols can reduce post-operative morbidity after major pancreatic resections with the adoption of peculiar clinical pathways [51-54]. Our clinical management is continuously evolving thanks to the contribution of clinical studies and can be resumed as following. Post-operative analgesia is obtained by continuous intravenous opioid infusion or by epidural catheter metameric anesthesia. Nose-gastric tube (NGT) is removed on post-operative day (POD) 0 or POD1 on the basis of its output. Patient can drink clear fluids on POD1 and eat a light diet on POD2 with progressive increase of the amount of food until oral diet is completely tolerated. On POD1 the patient is mobilized on a chair and further mobilization is encouraged over the following days. On POD2 or POD3 urinary catheter is removed. Central venous catheter is removed on POD4 or POD5. Patient is discharged when is able to tolerate oral diet and when post-operative pain is easily controlled by oral medications.

We do not promote an excessive intravenous post-operative fluid overload, as it can lead to submucosal intestinal edema, decreased blood flow and decreased tissue oxygenation resulting in a possible eventual anastomotic failure. Our recommendation is to use a balanced fluid restricted intake guided by the body weight (usually 25-30 ml/kg) and fluids loss. The best way to obtain this goal is to stop intravenous fluid as soon as possible and shifting to oral intake of fluids and medications.

COMPLICATIONS

Regardless of the indication, PPPD results in a peculiar pattern of complications. The most common one is represented by POPF, with an incidence rate ranging from 10 to 30% [21, 23, 55-61].

POPF can be associated with intra-abdominal fluid collections/abscesses, sepsis, hemorrhage, and, sometimes, re-laparotomy. Successful management of a POPF depends on its early identification and effective external drainage. Our group has demonstrated that an amylase value in drains ≤ 5000 U/l on POD1 identifies a subset of patients who are not likely to develop POPF and in whom continued drain management beyond the early postoperative period may be detrimental [62]. As a result of a randomized controlled trial we have determined that removing drains on POD3 is associated with a significantly decreased rate of

POPF, abdominal complications, and pulmonary complications [63]. Considering current available evidence, we recommend the prophylactic use of somatostatin analogues in order to reduce the risk of POPF [64]. At our Institution, somatostatin analogues are administered by POD0 (at the dose of 0,1 mg 3 times a day) until drain removal in non-complicated pancreaticoduodenectomy. In case of POPF, somatostatin analogues can be administered in order to reduce the entity of a high output POPF only in cases where infected POPF can be ruled out. The use of somatostatin analogues in case of infected POPF is not recommended. Therapeutic use of somatostatin analogues is not considered as an evidence-based approach yet because they are neither able to reduce the incidence of POPF grade B or C nor able to reduce the associated mortality.

Other important surgical complications are widely described in the literature. These are represented by post-pancreatectomy hemorrhage (PPH) [65], postoperative biliary fistula, delayed gastric emptying [66].

Nevertheless, appropriate drains management, optimal pain care, correct fluid administration, early oral nutrition and patient mobilization, represent key factors in order to reduce postoperative morbidity and the length of in-hospital stay.

MORBIDITY AND MORTALITY

Compared with PD for PDAC, PD for DBDC is associated with a different distribution of post-surgery morbidity. Usually, in case of PDAC, PD has a relatively low incidence of POPF. There are a lot studies that explored this aspect. Overall morbidity reaches 50%, where POPF account for around 15%, DGE for 13%, intra-abdominal collections for 16%, biliary fistula for 5% and Post-Pancreatectomy Hemorrhage (PPH) for 7% [67].

Our series of resected DBDC shows an overall morbidity rate of 66%, with consequent POPF rate of 45%, DGE 9%, intra-abdominal collections 32%, biliary fistula 7% and PPH at 19% (table 3). We can speculate that the high incidence of PPH, biliary fistula and intra-abdominal collections is directly related to the higher incidence of POPF. Post-operative pancreatic fistula is found to be related to specific factors, such as intraoperative blood loss, pancreatic remnant texture, pancreatic duct diameter, and histology of the primitive tumor [68]. With the exception of intraoperative blood loss, all the other three factors are related to obstructive pancreatitis. In fact, PDAC often produce an obstructive pancreatitis that leads to pancreatic duct dilatation and pancreatic remnant hard texture. DBDC, on the contrary, is often diagnosed at an early stage, because of early symptoms. The higher incidence of POPF for PD for distal bile duct cancer is related to the lack of obstructive pancreatitis in most of cases. Despite the morbidity rate, in our experience we found no mortality out of 74 cases.

SURVIVAL

High-volume centres report an overall 3- and 5-years survival ranging between 33 and 63% and between 16 and 52% respectively [30]. Surgical margin status has been reported to be a significant independent prognostic factor [69]. Curative R0 resection is mandatory in order to achieve long-term survival in DBDC.

Curative resection rates for DBDC are relatively higher than those for perihilar cancer [3].

The reason for such a poor prognosis for resected DBDC might be its locoregional and distant metastatic spread, which can occur at various times after surgery. Local recurrence along the biliary tree has been reported to be more common than distant recurrences in DBDC [70]. Therefore resection margin and perineural invasion are found to be strong independent predictors of survival [30, 41, 49, 71, 72].

Table 3.

	PD for distal bile duct cancer*	PD for ductal adenocarcinoma [from [67]]
POPF	45%	15%
DGE	9%	13%
PPH	19%	7%
Intrabdominal collections	32%	16%
Overall morbidity rate	66%	50%

POPF: Post-Operative Pancreatic Fistula; DGE: Delayed Gastric Empty; PPH: Post-Pancreatectomy Haemorrhage.

*Unpublished data (n=74) - General Surgery B - Institute of Pancreas, University of Verona

CONCLUSION

Although encouraging results have been reached in diagnostic imaging, surgical technique, perioperative care and pathological assessment, distal cholangiocarcinoma still remains a disease associated with a poor prognosis. Gold standard surgical treatment is represented by pancreaticoduodenectomy with achievement of an R0 resection. It should not be underestimated that pancreatic surgery is a high-risk surgery and that it should be managed only by high-volume centres.

Key Sentences

1. Distal cholangiocarcinoma is a rare malignancy, but thank to early symptoms, it must be diagnosed in early stages
2. When dealing with a resectable mass do not try to obtain an histological confirmation, preoperative work-up must focus on cancer staging and resectability assessment
3. In case of obstructive jaundice the select the patient for preoperative biliary drainage (endoscopic drainage is preferred; choose plastic stents unless you have ruled out surgical unresectability) on the basis of the correct indications (cholangitis, malnourishment, long-standing jaundice, renal insufficiency)
4. Fast-track protocols and clinical pathways should be adopted a safely used also in case of extensive surgical procedure to reduce hospitalization, morbidity and costs
5. Pancreaticoduodenectomy for distal bile duct cancer has a higher morbidity rate because of the presence of a “healthy” pancreatic remnant

6. Radical resection to obtain negative resection margin is a key point to increase chances of survival
7. Lymphadenectomy has a staging purpose and should be performed systematically by collecting at least 11 lymph nodes
8. Cholangio-Wirsung MR (CWMR), Contrast-Enhanced Ultrasound CEUS), CT-scan, Endoultrasonography (EUS) and Endoscopic retrograde cholangio-pancreatography (ERCP) are complementary techniques, sometimes all necessary for correct surgical assessment, according to different clinical situations
9. Surgery for distal cholangiocarcinoma should be performed only by high-volume centers or by well-trained surgeons

King Hussein Medical Center, Amman, Jordan

ABSTRACT

Kyphosis is a progressive, curvature of thoracic spine which results in rounding or bowing of the back . Curved spine accompanied by restricted neck motion and poor lung reserve present challenges for an ophthalmic surgeon who is used to patient's neck and head resting flat on the operating table and the eye in the horizontal position. Intraoperative difficulties include poor view, inability to maneuver surgical instruments properly and constant threat of elevated vitreous pressure. Several innovative solutions have been published including, maximal reverse Trendelenburg position with pillows under the head and neck, use of a donut and wedge shaped head positioner, allowing the patient to remain in upright sitting position while their head is positioned horizontally in a modified waiting room chair, performing surgery while standing, using 4-section orthopedic operating table, laying the patients on their sides, *side saddle* positioning, face-to-face positioning, parachute type harness inferior corneal retraction suture, or extreme patient positioning for retinal surgery. This chapter highlights various surgical options to facilitate surgeons pick the best course of action when dealing with intraocular surgery in patients with kyphosis.

Keywords: intraocular surgery, kyphosis

INTRODUCTION

Intraocular microsurgery mandates comfortable seating of both the patient and the surgeon at the start of the surgery. If either of these pre requisites is compromised, the ensuing suboptimal view of the eye may result in a high chance of intraocular complications. Patients with kyphosis present multitude of challenges related to their physical disabilities including concomitant pulmonary and cardiovascular diseases [1]. Several practical solutions have been described by very experienced surgeons but complications may still occur [2].

Gordon et al were able to successfully complete cataract surgery on a patient with severe kyphosis by using three pillows under his head and neck and 11 pillows under patient's buttocks and legs with the operating table positioned in maximum reverse Trendelenburg position [3]. They stressed that pillows be securely taped to the operating table to prevent slippage. A wedge-shaped pillow with built-in donut for positioning of the head and back [Profex Medical Products, St. Louis, MO] has been used by some surgeons [4]. This allows patient's head to be extended forward thus making the eye more accessible for surgery. They recommended using more than one of these positioners in severe cases. The depth of the doughnut helps to fix as well as elevate the head.

Fine and associates modified a common waiting room chair, for less than \$ 200, to accommodate patients with various back and head disabilities and enable these patients to remain in an upright seated position and tilt their head back [5]. The back cushion of the chair was placed on adjustable brackets. The legs of the chair were shortened to allow the patients to stretch their legs out in front to counterbalance the tilted position of the back and head. An adjustable head rest clamp was attached to the back of the chair to provide firm support. Extra stability was provided by a spindle attached to a strut between the front legs of the chair for counterbalance. Authors felt that their patients did not experience the cognitive and anoxia related symptoms in a supine position.

Another approach suggested performing cataract surgery standing up using loupes for magnification and fiber optic headlamp for coaxial illumination and making an infero-temporal scleral tunnel [6]. This surgery was complicated by posterior capsular tear requiring anterior vitrectomy. The surgeons were also unable to remove sub-incisional cortex because of shallow anterior chamber secondary to elevated posterior vitreous pressure. Poor visualization and unaccustomed standing position may have contributed to the complications. Hunter was able to remove cataract in an obese patient by performing phacoemulsification while standing but needed an ophthalmic technician to control focusing and side movements of the microscope [7]. A national survey of ophthalmic surgeons in United Kingdom reported that over 50% did perform cataract surgery while standing, if required [8]. A prospective study in England also showed that standing phacoemulsification was as safe as conventional surgery in the hands of experienced surgeons provided patient specific measures were taken [9].

Prasad et al recommended using a 4-section orthopedic operating table to enable an extreme reverse Trendelenburg position for cataract and glaucoma surgery [10]. However, because of blurred vision, they were unable to perform curvilinear capsulorehexis and had to resort to can-opener capsulotomy. Sambandam was able to complete cataract surgery on a patient with severe kyphosis by laying her on her side [11]. This patient was unable to lie on her back at all. A side saddle approach was described by Nair et al where in the surgeon sat

with his thighs parallel to the long axis of the operating table and facing the head end [12]. The optical axis of the microscope had to be inclined about 60° towards the horizontal. The globe was tilted superotemporally to optimize red reflex. They used intra cameral anesthesia and infero-temporal corneal incision which may increase incidence of endophthalmitis. When the patient can only be placed in a semi recumbent position, Ang et al have proposed a face-to-face sitting position and tilting the operating microscope 60° from the vertical [13]. Surgeon has to be aware and adjust for the unsteadiness caused by outstretched arms. Topical anesthesia allowed the patient to comply with requests to fixate on the microscope light. Some patients may need strong parachute-like support harness for secure positioning [14]. The surgeons used foam to support the head, neck, shoulders and knees and moved the table in extreme Trendelenburg position. They used Velcro surgical straps similar to straps in a parachute harness. Cataract was removed via a superotemporal corneal approach under retrobulbar anesthesia. Elevated legs may distend jugular veins and result in increased posterior pressure.

We described a 49- year-old obese male with controlled secondary glaucoma who needed cataract surgery in the right eye [15]. He had ankylosing spondylitis related extreme kyphosis and neck in fixed flexion (Figure 1). His pulmonary reserve was also very low. The past ocular history was positive for recurrent uveitis and glaucoma shunt surgery in the right eye. The pupil was small and fixed from posterior synechia. The cataract was +4 dense. The best corrected visual acuity was 20/200. The anterior chamber was shallow and glaucoma tube shunt was visible at 11 o'clock position. The pre-op plan included pupillary dilation with iris retraction hooks, corneal staining with trypan blue, and phacoemulsification with intra ocular implantation under local anesthesia. The anesthesiologist was reluctant to use general anesthesia because of patient's disability and poor health.

Figure 1. The patient with kyphosis and immobile neck in fixed flexion.

In the operating room, the patient could only recline to about 40° from the vertical axis despite maximal reverse Trendelenburg position and number of pillows under his back, neck, head and legs (Figure 2). With the surgeon at the temporal side of the patient, the eye was also seen reclining at 40° (Figure 3). While trying to focus the microscope, it became evident that by grasping the eye at the inferior limbus with a fine forceps, and pulling it upwards, the

eye could be moved to a more desirable horizontal position. A single 7/0 Vicryl (polyglactin) corneal retraction suture was placed at the limbus at 6 o'clock position to achieve the desired view (Figure 4). The assistant was able to rotate the eye to the desired positions during the whole procedure by relaxing or pulling on the suture (Figure 5). There were no intra-ocular complications and the post-operative recovery was uneventful. The final best corrected visual acuity was 20/30.

Figure 2. The position best tolerated by the patient during surgery.

Retinal surgeries are often more complex and require longer duration than cataract surgeries. You and associates [16] employed the head-down position with cushioning support in a man with severe 90 ° curvature of his spine. They used three large orthopedic cushions and several pillows to raise the patient's legs by approximately 48 ° and secured the patient with ample surgical tape and three straps. The operating microscope had to be tilted at 15 ° offset. The team was able to complete the very complex retinal procedure without any complications.

Figure 3. The virtual vertical position of the eye at the beginning of surgery.

Figure 4. Pull on the corneal retraction suture (white arrow) allowed rotation of the eye more horizontally.

Figure 5. Cataract surgery was completed successfully. Iris retraction sutures kept the pupil dilated.

In a patient with severe thoracic kyphosis who was unable to lie flat on a table, Razeghinejad et al used a chair with adjustable top between an operating table and another small table [17]. The wheels of the table and the chair were secured with adhesive tape. The patient was laid with his head on the small table and his thorax fitting on the well-padded chair. The adjustable top of the chair allowed accommodating kyphotic thorax. The cataract surgery was performed successfully. Packer recommended making an extra paracentesis inferiorly to assist in capsulorehexis but the relatively vertical position of the eye still made this procedure difficult [18].

CONCLUSION

Patients with kyphosis may present several unique challenges to an eye surgeon. The foremost being the inability to lay the head and neck in the ideal horizontal position. The resulting poor view makes focusing and manipulation of tissues and instruments difficult. Tilting the head end of the operating table down and raising patient's legs may compromise venous return from the orbit causing venous engorgement and elevated posterior vitreous pressure during surgery. In addition, patient's poor pulmonary reserve itself may further impede orbital/jugular venous return resulting in increased posterior vitreous pressure [14, 5, 6, 9]. Afshar et al have proposed an in-office trial of Trendelenburg positioning by inclining an office examination chair to determine head position while supine [19]. Other features of kyphosis that may adversely affect intra ocular surgery are tenderness and stiffness of the back and difficulty breathing. It is imperative that the anesthesiology and nursing staff be alerted and consulted for team work. Most experts have recommended topical, intracameral anesthesia rather than general anesthesia in patients with kyphosis [12, 19, 20]. Topical anesthesia allows the patient to fixate on the operating light, keep the eye in the desired position and obtain the best red reflex. Other helpful maneuvers are, turning the patient's face and /or chin up, standing temporal approach and using straight instruments rather than curved to avoid damaging intraocular structures [20]. In short, there is no single solution for these groups of difficult patients. Careful pre-op evaluation, planning and a team approach with internist, anesthesiologist, nursing staff is paramount. A surgeon may use one or more proven ways to deal with the issues at hand. Besides kyphosis these suggestions may also be helpful in other conditions causing inability to recline such as torticollis [21], chronic obstructive pulmonary disease, chronic congestive heart failure, morbid obesity, myotonic dystrophy, ankylosing spondylitis, cerebral palsy, Meniere's disease or claustrophobia. Surgeons may consider operating on these patients earlier when the cataract is softer rather than later to avoid complications associated with advanced hard cataracts.

Chapter 362

SURGERY OF THYMOMATOUS MYASTHENIA GRAVIS

Cameron D. Wright*

Division of Thoracic Surgery, Massachusetts General Hospital,
Boston, MA, US

ABSTRACT

About 21% of patients with myasthenia gravis have a thymoma and about 50% of patients with a thymoma have myasthenia gravis. Patients with thymoma-associated myasthenia gravis tend to be younger than thymoma-alone patients and tend to have World Health Organization type AB, B1 or B2 thymomas. Resection with an extended thymectomy is generally the treatment of choice. Whereas in the past myasthenia gravis was thought to lead to a worse prognosis, recent series suggest either a better or equivalent prognosis. The neurologic results tend to be worse than those reported for pure myasthenia gravis after extended thymectomy. Myasthenia gravis may appear late after resection of a thymoma not associated with myasthenia gravis, independent of any recurrence of the thymoma.

INTRODUCTION

The incidence of thymoma in patients with myasthenia gravis (MG) has been reported to vary between 11 and 60% in large case series [1]. A recent systematic review of 49 articles covering over 6000 patients reported an incidence of 21%, with population-based studies at 17%, hospital-based studies at 12% and surgical series at 25% [1]. Further analysis of these patients indicated that male gender (Odds ratio [OR] 1.78) and age > 40 (OR 5.74) were risk factors for myasthenia patients to present with a thymoma.

Given the well-known association of MG and thymoma it is standard practice to screen for a thymoma when MG is first diagnosed. The most commonly ordered exam is a contrast-

* Corresponding Author's Email: cdwright@partners.org.

enhanced CT. Alternatively, a mediastinal magnetic resonance (MR) exam can be ordered which has the advantage of no radiation exposure to the patient. This is especially useful for children and young woman. Furthermore, MR is very good at distinguishing thymic hyperplasia from an early thymoma which is an occasional clinical concern [2]. The disadvantages of an MR exam is that it is more costly and has a higher dissatisfaction rate with patients due to the length of the exam, noise and the close confines of the machine.

Large case series of thymoma patients report an incidence of MG at presentation of 40-50%. A recent large multicenter study of 537 patients with thymoma reported an incidence of MG in 51% of patients [3]. This study also reported that thymoma patients with MG were more likely to have an early stage tumor and have WHO type B histology compared to A histology [3].

PREOPERATIVE PREPARATION

The preoperative preparation for patients undergoing surgery for a thymoma associated with MG is the same as those without a thymoma. Close cooperation between the neurologist and thoracic surgeon is mandatory and the patient should be in optimal condition before operation to minimize the risk of postoperative complications related to poor myasthenic control. An operation is a stressful event and is a known risk factor for a myasthenic crisis. A recent study reported on the risk factors for myasthenic crisis after thymectomy in 178 patients [4]. Multivariate analysis indicated that preoperative myasthenic crisis (OR 2.8), presence of bulbar symptoms (OR 3.1) and longer operations (OR 1.1) were risk factors for a postoperative myasthenic crisis [4]. One recent intriguing study reported on the efficacy of high-dose prednisolone therapy perioperatively to reduce postoperative myasthenic crisis. This was an observational study that was not randomized. Seventy patients had steroids and 61 patients did not in a group of patients with MG, with and without thymoma. Patients who had steroids had a reduced rate of postoperative myasthenic crisis (12% vs 3%, $p=0.045$) [5].

SURGICAL TECHNIQUE

The standard operation for a thymoma associated with MG is a complete resection of both the thymus and the thymoma. Most surgical series report that an R0 resection is one of the most, if not the most important predictors of long-term survival after thymoma resection [3]. The surgeon must carefully review the preoperative imaging to determine the estimated clinical stage of the patient. Predictors of invasion include large size, edge characteristics that suggest invasion and a lobulated contour [6]. Induction chemotherapy should be administered for invasive tumors that appear marginally resectable. The operative approach depends on the stage, location and experience of the thoracic surgeon. Small early stage thymomas can be resected by essentially all operative approaches as described in other sections dealing with non-thymomatous MG.

The “standard” operation is a transsternal resection of both the thymus and the thymoma and has stood the test of time. Large tumors involving the lung are sometimes best resected with a hemi-clamshell approach. Minimally invasive approaches have been reported with

increasing frequency and enthusiasm with intermediate term results essentially equivalent to those of the standard trans-sternal approach [7,8].

Most recurrences of thymomas occur between years 5 and 10 and thus long-term follow-up is needed to ascertain the results of any surgical approach. Minimally invasive resection of invasive thymomas has been reported as well in more limited numbers [9]. One center reported an apparent advantage of robotic thymectomy over VATS thymectomy in terms of MG regression although it was a retrospective study [10]. In the end, as long as a complete resection of both the thymus and thymoma is accomplished the results should be the same between the 2 approaches.

Certainly there is increasing enthusiasm for minimally invasive resections of thymomas, regardless of whether myasthenia is present or not. In general, the early results suggest less blood loss, less pain, shorter hospital stays and earlier return of baseline physical status. These early results however must be tempered against the long-term results, especially the recurrence rate and the complete remission rate.

To date, I am unaware of any large series with reported 10 year results after minimally invasive resection of thymomas. I suspect they will be essentially the same as with open approaches but there will be the rare patient that had some inadvertent spillage during the resection that recurs unexpectedly late in the pleural space. I have seen 2 such patients in the past 10 years who were operated on by expert surgeons elsewhere by VATS for early stage I thymomas with early pleural recurrence. It is important not to grasp the tumor itself when attempting a minimally invasive resection to avoid inadvertent capsular disruption.

Consideration should be given to have either a trocar or a wound protector in all access sites to reduce the chance of a port recurrence. Of course a plastic bag should be used and closed before the specimen is removed. The surrounding mediastinal fat can be used as holder to facilitate resection. A recent case report of a port site recurrence after VATS resection of a stage I thymoma illustrates what can happen after a seemingly uncomplicated resection of an encapsulated thymoma [11]. A recent review article summarized the series reported as of 2011 comparing VATS and trans-sternal thymectomy for MG [12].

Tables 1 and 2 summarize this review. Table 1 reports the important metrics in nonthymomatous MG between VATS and trans-sternal thymectomy. Overall the operating time was a little longer, the remission rate was a little less (but the p was 0.16), while the blood loss and hospital stay were less. The complication rates and amount of thymic tissue resected were similar. Table 2 reports the outcomes in mixed thymomatous and non-thymomatous MG patients between VATS and transsternal resections. VATS patients had less need for an ICU, decreased length of stay and less need for pain medication. VATS patients had longer operations and the patients perceived a better cosmetic result along with improved symptoms of MG.

My overall thoughts are that many small clinically encapsulated thymomas can be removed safely by VATS, but if the surgeon has any concerns the resection should be done by an open approach. I still think that invasive tumors are generally best resected with an open approach. However it is clear this field is evolving and no universal consensus has been reached on the best technique.

Table 1. Outcomes in nonthymomatous myasthenia gravis between VATS and transsternal thymectomy based on 6 studies [12]

Approach	OR time (minutes)	EBL	LOS days	Complications	Remission	Thymic mass resected	Postop. mortality
VATS	268	74ml	5.6	23%	33%	37 g	0
Sternotomy	177	155 ml	8.1	19%	45%	34 g	0

VATS=Video-assisted thoracic surgery, OR=Operating room, EBL=Estimated blood loss, LOS=Length of stay.

Table 2. Outcomes in mixed thymomatous and nonthymomatous myasthenia gravis between VATS and transsternal resection based on 8 studies [12]

Approach	OR time (minutes)	ICU stay (days)	LOS (days)	Narcotic need (rate)	Cosmetic satisfaction	Symptom improvement	Postop. mortality
VATS	268	1.5	1.9	36%	100%	100%	0
Sternotomy	177	3.2	4.6	77%	83%	78%	0

VATS=video-assisted thoracic surgery, OR=Operating room, ICU=Intensive care unit, LOS=Length of stay.

Figures 1 and 2 demonstrate two early stage thymomas that were resected by a VATS technique. Figures 3 and 4 demonstrate two locally advanced thymomas that had induction chemotherapy followed by an open resection. These are easy cases to stratify between a minimally invasive and open approach. The many cases in between require a great deal of judgment and a consideration of the skill and philosophy of the surgeon to decide on a particular approach.

Figure 1. Small midline thymoma with sharp borders and a clear tissue plane between the thymoma and the aorta, clinically not invasive. Pathology revealed a Masaoka stage 1, WHO B2 thymoma. This was removed by VATS.

Figure 2. Small right sided thymoma with sharp borders, clinically not invasive. Pathology revealed a Masaoka stage I, WHO AB thymoma. This was removed by VATS.

Figure 3. Large lobulated heterogenous thymoma with areas of necrosis and calcification and invasive borders. Pathology revealed a Masaoka stage III, WHO B3 thymoma. This was removed by mediansternotomy after induction chemotherapy. The pericardium, phrenic nerve and lung were resected along with the thymoma.

Figure 4. Large invasive thymoma with encasement of the innominate vein and invasive borders. Pathology revealed a Masaoka stage II thymoma, WHO B3 thymoma. This was removed by mediansternotomy after induction therapy. The innominate vein was resected and a superior vena cava resection and reconstruction was required.

One particular issue frequently comes up during resection of thymomas associated with myasthenia gravis—that of preserving the phrenic nerve. Thymomas frequently abut the phrenic nerve as they enlarge and drop down into the affected pleural space. If the nerve is clearly invaded and the diaphragm is known to be paralyzed preoperatively the intraoperative decision is easy—cleanly resect the nerve to enhance the R0 resection. More difficult is when the nerve is abutted but not clearly invaded. Many surgeons will then skeletonize the nerve, mark it with clips for possible adjuvant radiation in an effort to maximize lung function and reduce the risk of respiratory failure.

Obviously when one nerve is significantly at risk every effort should be made to not put the other phrenic nerve at risk. One recent paper tried to address this important issue [13]. One-hundred fourteen patients with Stage III and IVA thymomas were studied. The phrenic nerve was either abutted or invaded in all. The phrenic nerve was spared in 73 patients and resected in 41. The indications for sparing the nerve were: both nerves involved, compromised lung function, severe MG, or severe comorbidities with close abutment. There was no difference in postoperative morbidity or mortality. A higher recurrence rate was observed in the phrenic nerve spared group (67% vs 54%) but there was no difference in overall or disease free mortality [13].

RESULTS

The perioperative results of thymoma resection in association with MG in the current era are essentially similar to patients without MG [3,14,15]. With current management strategies that emphasize close cooperation with a neurologist and optimal preoperative preparation myasthenic crises are rare after operation. A recent study reported on the predictors of a myasthenic crisis after thymectomy. Multivariate analysis suggested that a history of preoperative myasthenic crisis, presence of bulbar symptoms and longer operation duration were predictors of postoperative myasthenic crises [4].

The long-term results of surgery can be separated into 2 aspects-freedom from recurrence and survival related to the thymoma and the response of the MG to thymectomy. The important predictors of freedom from recurrence and long-term survival are well known in thymoma; an R0 resection, Masaoka stage and World Health Organization (WHO) histology [16]. A generation ago the thought was that thymoma associated with MG led to a worse prognosis, largely due to poor neurologic outcomes. However the medical care of myasthenic patients has significantly improved over the past 20 years. Several recent series suggest a slightly better survival of thymoma patients with MG than those without MG [17].

However a recent large multi-institutional series of 2,151 patients reported in a multivariate analysis that MG had no significant effect on overall or disease-free survival [16]. Many clinicians think that MG patients often have an earlier diagnosis of thymoma leading to slightly better results. However with proper statistical analysis after matching of all important covariates it seems likely that there is no significant survival difference in thymoma patients with and without MG.

In general, most series report that remission from MG associated with a thymoma is worse than patients without thymoma, generally with a complete remission rate of only 10-15% [17,18]. A relatively recent report on 123 patients with MG and thymoma resected with an extended thymectomy however reported a 43% complete remission rate at 5 years, similar to reports with MG alone [14]. This study also reported an intriguing result-that patients who achieved a complete remission had a better oncologic prognosis. It is hard to reconcile these disparate results though one could argue that careful attention to an extended thymectomy (in addition to an R0 resection of the thymoma) is likely to lead to better MG neurologic results and a less complete thymectomy could be the reason for suboptimal results.

MG symptoms may be exacerbated after resection of a thymoma (and thymectomy) and lead to a need for enhanced medical treatment of the MG and occasionally lead to a

myasthenic crisis [4,20]. MG may also appear in the late postoperative period after resection of a thymoma not associated with preoperative MG [4,20,21]. The incidence in larger series ranges from 5-10% [18,21]. There appears to be no association with the WHO histology of the thymoma and late postoperative MG. The majority of cases of late postoperative MG are not associated with a recurrence of the thymoma. Alternatively, a thymoma may develop late after thymectomy for nonthymomatous myasthenia gravis, despite a reported “complete” thymectomy [22]. Presumably this is due to thymic rests in the unresected mediastinal fat that later develop into a thymoma.

Patients with myasthenia gravis and thymoma need long-term follow-up, both for medical management of myasthenia and to monitor for a possible recurrence of the thymoma. The outlook is overall quite favorable and in large series the 5 year survival is 93% and the 10 year survival is 80% in patients with MG and thymoma [14].

CONCLUSION

About 21% of patients with MG have a thymoma and about 50% of patients with a thymoma have MG. Patients with thymoma-associated MG tend to be younger than thymoma-alone patients and tend to have WHO type AB, B1 or B2 thymomas. Resection with an extended thymectomy is generally the treatment of choice. Optimal preoperative preparation of the underlying MG is very important. Resection of early stage thymomas can be done by either VATS or an open approach depending on the details of the thymoma and the expertise of the surgeon. Locally advanced thymomas are usually resected by an open approach.

Whereas in the past MG was thought to lead to a worse prognosis, recent series suggest either a better or equivalent prognosis. The neurologic results tend to be worse than those reported for pure MG after extended thymectomy. MG may appear late after resection of a thymoma not associated with MG, independent of any recurrence of the thymoma. Long-term survival at 10 years approaches 80% in patients with combined MG and thymoma.

Chapter 363

PALLIATIVE HIP SURGERY IN PATIENTS WITH CEREBRAL PALSY

Julio Duart-Clemente^{1,*} and Serafín García-Mata¹

¹Paediatric Orthopaedic Dept., Navarra Hospital Complex,
Pamplona, Spain

ABSTRACT

The painful dislocated hip in cerebral palsy cases is a challenging problem. The incidence of hip subluxation or dislocation in CP is reported to be between 20% and 60% and is most common in the higher Gross Motor Function Classification System (GMFCS) levels. The cause of the dislocation is clearly multifactorial. Several changes have been described in patients with dislocation of the hip. The muscle forces combined with acetabular dysplasia lead to dislocation and degenerative changes in the femoral head. These degenerative changes can be painful and affect the patient's quality of life and levels of nursing care required. Dislocation of the hip usually produces changes in the position, represents a major nursing dilemma and can lead to ulceration. The treatment of hip dislocation in patients with CP remains controversial. Salvage procedures may be appropriate for hips that cannot be reconstructed; but, the key is to identify the most appropriate surgical technique for each patient. The most common procedures are: femoral head resection, femoral head resection and subtrochanteric valgus osteotomy, proximal femoral resection-interposition arthroplasty, total hip replacement and hip arthrodesis.

Keywords: hip, cerebral palsy, palliative surgery, dislocation, resection, arthroplasty

KEY POINTS

- The painful dislocated hip in cerebral palsy cases is a challenging problem.
- The cause of the dislocation is clearly multifactorial.

* Corresponding Author's Email: duart.julio@gmail.com.

- Surgical treatment should be placed in three main categories: resection procedures (proximal femoral resection arthroplasty, subtrochanteric valgus osteotomy, with femoral head resection and interposition arthroplasty), total hip arthroplasty and hip fusion.
- The most significant complications that we can present after palliative surgery we highlight persistent pain and chronic pain syndrome.
- There are many methodological difficulties in measuring the functional outcomes of these procedures.
- Although surgical treatment is mandatory in case of painful spastic hip, it is difficult to determine which is the best treatment.

1. INTRODUCTION

The incidence and spectrum of hip abnormalities in children with cerebral palsy vary greatly. The painful dislocated hip in cerebral palsy cases is a challenge. Dislocation can be painful because of hypertonia and may impair care-giving, seating, positioning and quality of life [1]. The cause of the dislocation is clearly multifactorial. Several changes have been described in patients with dislocation of the hip. Muscle forces combined with acetabular dysplasia, persistent femoral anteversion and increased neck-shaft angle lead to dislocation and degenerative changes in the femoral head. These degenerative changes can be painful and affect the patient's quality of life and levels of nursing care required. [2]

In the normal hip, balanced muscle use promotes the symbiotic development of the acetabulum and femoral head. Upright posture and ambulation promotes remodelling of neonatal femoral anteversion. Children with cerebral palsy are born with normal hips. However, these hips are soon subjected to abnormal muscle forces that lead to hip abnormalities. The combination of spastic muscle activity and altered sitting posture redirects the femoral head to the superolateral and posterior aspects of the acetabulum.

With progressive subluxation, the femoral head presses up to the lateral edge of the acetabulum. The lack of mobility and increased pressure on the medial aspect of the femoral head leads to flattening and a loss of sphericity. The upper portion of the femoral head remodels and the articular cartilage of the femoral head is worn away. Dislocation of the hip usually produces changes in position with the patient holding the lower limb in adduction and flexion. These changes may result in difficulty sitting in a good position.

Dislocation also represents a major nursing dilemma. Indeed it can make it difficult to ensure adequate perineal hygiene care due the limitation of the adduction of the hip. (Figure 1) The deformity can also cause overload in some areas of the skin (such as the isquium and sacrus) that can lead to ulceration. Patients with hip dislocation commonly have a tilted pelvis as well as scoliosis and a higher risk of femur fracture [3].

It is extremely difficult to appreciate if a dislocated hip is painful due to the usual lack of expression of patients with severe neuromuscular compromise (GMFCS IV and V). Often the opinion of parents and caregivers is very important, such as changes in facial expression or sounds of grievance can be very useful signs to determine if the dislocated hip is painful.

Figure 1. A. Male, age 11+6, spastic *quadriplegia*. He presents impossibility for abduction of the left hip and difficult for nursing and daily care. B. Initial pelvic radiograph Subluxation of the right hip and dislocation of the left hip.

The treatment of hip dislocation in patients with CP remains controversial [1]. The recommended treatment depends on the patient's hip function and somewhat on their size and general health. In young patients or adolescents who present with pain in the absence of degenerative signs on the hip, we can try conservative treatment including restricting physical activity, rehabilitation and pain-killers.

If the pain is not remedied rapidly, surgical treatment may be indicated. It's important to determine the goals of palliative treatment for the dislocation of hips. The main goal is to relieve pain resulting from dislocation of the hip. Having achieved the main goal, we can focus on secondary objectives related to the patient's functionality such as achieving a stable joint, increased range of motion attempting a better sitting position and walking if possible.

Surgical treatment should be placed in three main categories: resection procedures (proximal femoral resection arthroplasty, femoral head resection with subtrochanteric valgus osteotomy, and interposition arthroplasty), total hip arthroplasty and hip fusion.

2. RESECTION PROCEDURE

Proximal Femoral Resection Arthroplasty (PFRA)

Resection of the femoral head and neck has been recommended for the treatment of patients in whom a congruous hip reduction is impossible due to an incongruity of the femoral head and the acetabulum following prolonged dislocation. Castle and Schneider [4] described a procedure in 1978 when they performed a subtrochanteric resection of the femur in twelve severely mentally and physically disabled children with dislocated hips and severe adduction of the lower limbs. Usually this procedure is indicated in very young patients with poor health [4, 5].

The deformity often interferes with perineal hygiene, nursing care and positioning in bed and in a wheelchair. After surgery all patient have an improved sitting position and passive range of motion of the hip, which facilitates care and hygiene.

In the original paper they described the surgical technique. After an extraperiosteal dissection they removed the entire femur, including head, neck and 3 cm of femoral shaft

distal of the lesser trochanter. This wide resection also detaches the abductors, gluteus maximus, iliopsoas, quadriceps and the capsule. After that this soft tissue can be inserted between the femoral shaft and the acetabulum. Generally, the recommended aftercare is for these patients to be kept in distraction traction for six weeks with traction of the lower limbs, to limit the proximal migration, until the soft tissue healed and resection was stabilized (Figure 2).

Figure 2. A. Male, age 15+2, spastic *quadriplegia*, Initial pelvic radiograph. B. Age 17+11, postoperative 2 +9years of Castle procedure both hip.

Baxter and D'Astous [5] published their experience with this technique in four patients with CP and painful spastic hip dislocations. They did not observe significant loss of motion, no bony ankylosis or impingement, no myositis ossificans, and no recurrence of pain. The postoperative results in terms of comfortable sitting were positive.

A variation of this technique was described by McCarthy [6] in 1988 for the treatment of adult patients. This variation was introduced with the intention of minimizing secondary complications due to the supine position needed for the traction in the Castle technique such as pressures sores, aspirations pneumonia, urinary stasis and gastrointestinal hemorrhage. After the resection of the proximal femur, the abductors and iliopsoas were sutured to the hip capsule and the femoral stump was covered with the vastus lateralis. In the original study the

author reported an improvement in the sitting capacity and range of motion in 33 of the 34 patients treated with this resection, with a minimum of two years of follow-up.

In 1999 Widman [7] published the Hospital for Special Surgery experience on PFRA as a salvage procedure for intractable pain or seating difficulty, consisting in thirteen patients (18 hips). Eleven patients (14 hips) had prior unsuccessful soft-tissue or bone reconstructions. The average follow-up was 7.4 years. All patients/caregivers noted significant improvement in the subjective assessment of pain following surgery, but resolution of pain may not have been immediate. There was an improvement in upright sitting tolerance and the range of motion of the hips. They recommend the use of radiation to prevent heterotopic ossification.

The largest series reported in the literature was by Muthusamy [8], a retrospective case series with a follow-up questionnaire. A sample of 27 patients was used with an average follow-up time of 7.8 years. They found an improvement in hip pain, range of motion, daily activities, and quality of life after surgery. They compared age at surgery, type of immobilization and presence of heterotopic ossification or femoral migration and did not find a relationship with the long-term surgical outcome.

Postoperative complications of these techniques include persistent pain, infection, decubitus ulceration, pneumonia and heterotypic ossifications. Some authors emphasize the importance of informing the carers that this procedure takes six to nine months postoperatively to achieve relief of pain [7].

Femoral Head Resection

Resection of the femoral head alone is described as the Girdlestone procedure and has been used to treat severe degenerative arthritis, especially prior to a total hip replacement. It is disputable whether the use of this technique is adequate in spastic hips, with only one report comparing the results of the Girdlestone procedure with Castle's results [9]. They reviewed retrospectively their experience in patients with symptomatic subluxation or dislocation of the hip that underwent proximal femoral resection arthroplasty presented. The sample consisted of thirteen patients (19 hips). The resections were performed at the level of the neck in nine hips and in the subtrochanteric region in 10 hips. They observed poor clinical results with no correction of the pre-operative pelvic tilt, the postoperative adduction contracture, and bone contact between the pelvis femur and heterotopic ossification. These results demonstrate that the Girdlestone is not as effective at relieving pain as the subtrochanteric resection.

In 1990 MacHale [10] described a modification of the resection of the femoral head associating a subtrochanteric valgus osteotomy. They performed this procedure on six hips in five non-ambulatory adolescent patients with CP which presented painful and dislocated hips. The operative technique described in the paper includes adductor release in all cases. Through an anterolateral approach of the hip a resection of the neck and head was done, then a close wedge subtrochanteric osteotomy was performed, the valgus position was maintained by internal fixation. Subsequently, the lesser trochanter was rotated into the acetabulum, and the capsulorrhaphy was performed. The aftercare included a spica cast for 3 weeks. All patients were able to sit for longer periods pain-free prior the surgery (Figure 3).

Figure 3. A. Female, spastic *quadriplegia*, Initial pelvic radiograph. B. Postoperative radiograph of McHale procedure both hip (courtesy Dr. Martínez Caballero).

In 2009 Van Riet and Moens [11] published their experience of this procedure; they conducted a retrospective study of adolescent and adult patients with cerebral palsy, affected by chronically painful and dislocated hips who underwent the McHale procedure between 1994 and 2004. They presented thirteen patients with seventeen procedures. All patients had pain at the time of the surgery, and most of them reported limitations in sitting and nursing care problems. All patients underwent clinical and radiological examination of the hips, and a questionnaire was answered by both parents and caretakers. The minimum follow-up was 23 months. They observed an improvement in all patients with respect to pain and higher sitting tolerance in 6 patients. Ten caregivers reported that it was easier to administer care. Although these results appear promising, they are not very optimistic about this procedure because of the high rate of complications, including heterotopic ossification, residual pain, hardware intolerance, fractures and pulmonary complications.

They concluded that procedure was successful because it led to pain relief, ease of perineal care, and facility of seating. The subtrochanteric valgus osteotomy is an excellent procedure for a hip that is pain-free but fixed in a poor position. There is however a high incidence of failure and complications.

Prosthetic Interposition Arthroplasty

One of the modifications after the proximal resection is the use of prosthesis. Prosthetic Interposition arthroplasty has been utilized in patients who have open growth plates, or patients who are non-weight-bearing. One noteworthy advantage of this technique when used in these patients is that traction was not needed after surgery. Descriptions in the literature are rare; in fact the only case series is that published by the DuPont Institute [12]. They have presented their experience in using a prosthetic arthroplasty for the treatment of painful degenerative arthritis in 11 non-ambulatory patients (14 hips) with CP. Clinical follow-up averaged 5 years. Ten patients (13 hips) had complete relief of hip pain. Carer satisfaction

was high for these patients, with all 10 carers stating that they would recommend the procedure. Only one patient continued to have persistent pain in the hip.

The implants prosthesis serves as a spacer between the bone ends. Different materials and devices have been used for interposition such as shoulder prosthesis, cement spacers, Poly methyl methacrylate (PMMA), silastic arthroplasty, etc. (Figure 4) Gabos recommended an interposition arthroplasty using a standard shoulder [12] or hip resurfacing implant.

Figure 4. Patient of the Figure 1. A. Resected specimen of the proximal femur. Note the triangular shape of the femoral head and extensive loss of articular cartilage on the medial, lateral, and superior surfaces. B. The handmade interposition device manufactured in Polymethyl-methacrylate (PMMA). C. Postoperative pelvic radiograph with a VRO of the right hip and a prosthetic interposition arthroplasty on the left hip.

One of the most important points about this treatment is that it is not crucial that the prosthesis remain in a reduced position, although an attempt is made during the operative procedure to suture soft tissue around it to hold it in the false acetabulum or real acetabulum. Gabos observed that ten of the hips remained located on the latest radiographs, and four of the hips dislocated within 4 months of the procedure. No patient exhibited migration or failure of

the implants, although one patient exhibited periprosthetic osteolysis, which remained unchanged over a 4-year period [12]. They presented intraoperative complications such as breakage of the tip of a femoral canal reamer inside the femoral shaft. And two patients sustained femoral fractures following the procedure, one patient on distal third of the femoral shaft and a second at the site of a previous midshaft femoral fracture.

The goal of surgery is to relieve pain and maintain some joint mobility. Some authors recommend placing a glenoid component when raw bone is observed. Following surgery patients should be kept with legs apart in order to place the joint in the correct position. For this we use an abduction pillow or the patient can be placed in the short broomstick leg cast with broomsticks. Usually these patients do not require traction. The results of this procedure have shown good pain relief that is more quickly effective than with the femoral resection [12].

Prosthetic interposition arthroplasty appears to be an effective surgical option for the treatment of a painful, subluxated or dislocated arthritic hip in non-ambulatory patients with severe spastic quadriplegic-pattern cerebral palsy.

Total Hip Arthroplasty

Total hip arthroplasty (THA) has changed the life of millions of people with painful hips since the early 1960s. As discussed by Root [13], orthopaedic surgeons have been reluctant to recommend the procedure for a CP person with a painful subluxed or dislocated hip. The questions were: would a hip replacement in a CP patient dislocate or loosen prematurely because of spasticity or athetosis? And would the procedure reduce pain and restore function in this group of patients?

THA is an alternative, but is an exceptional indication. The risks of dislocation, ectopic ossifications and infection often refute this indication. THA may be indicated for patients who are able to stand and bear weight for transfers or home care, and definitely for individuals who are community paramedics. This procedure provides the most stable joint, and in adults or young adults, it can be done with acceptable risk. The goal of THA for the paralytic hip is to obtain a painless joint which is as mobile as possible with recovery of the functional level prior to joint degeneration. It is however important to note that THA does not produce any improvement in the patients' functional capacity. As normal hip function is not the goal in patients with a paralytic joint, it is important to take into full account the patient's motor capacity (Figure 5).

Weber and Cabanela [14] reported on 16 patients with 16 hip replacements. Eighty-seven percent of the patients had pain relief, and ambulatory function improved in 79%. They had no dislocations, and complications were rare.

Root et al. [13] published results on THA in CP, the survivorship was 95% for 10 years, and preoperative pain was relieved in 94% of the patients. These studies confirm that THA is a safe and successful procedure for painful hips in the cerebral palsy population, even in younger age groups and even in those who function mainly in a wheelchair.

Recently, Schroeder et al. [15] reported eighteen THAs in 16 ambulatory patients with cerebral palsy. There was a significant postoperative reduction in pain on the NAS (narrative analogue scale), the mean follow-up was 10 years (range 2–18 years) and at follow-up no stem had been revised. Three cups were revised for aseptic loosening at two and six years,

and one cup was revised for recurrent dislocation of the hip. One hip was revised for infection 12 years after the index surgery. One hip dislocated (three months postoperatively) and was treated by closed reduction.

Figure 5. A. Female, age 16+6, spastic *quadriplegia*, Initial pelvic radiograph. B. Age 17+3, postoperative 6 month of left Total Hip Replacement.

The largest series published in the literature was in 2010 by Raphael et al. [16], relating to patients of the Hospital for Special Surgery (New York, USA), a retrospective study of 56 patients (59 hips) with CP who had THAs for painful hips, patients or caregivers completed a questionnaire, including a modified Gross Motor Function Classification System mobility scale and qualitative reports of pain and satisfaction. All patients have pain relief. Seven patients underwent acetabular component revisions, and two patients had a femoral stem component revision, the 10-year survivorship was 85%.

Prior to surgery is important to consider that the primary underlying pathological mechanism is muscle imbalance with the strong hip flexors and adductors overpowering the weaker abductors and extensors, resulting in contractures and bone abnormalities include excessive valgus of the femoral neck and persistence of fetal anteversion and acetabular dysplasia. These changes may affect the stability of the implant and make necessary modifications to the standard surgical techniques including the use of custom-made femoral

implants, tenotomies, hip spicas and placing the acetabular component in anteversion for sitters.

Many reports in the literature [13, 14, 17] conclude that the major complication of THA replacement is the risk of dislocation. All the dislocations were probably secondary to motor disorders induced by the transient disruption of periarticular muscle activity due to surgery [13] and recurrent dislocation due to incorrect implant orientation that were successfully treated by changing the prosthetic components [17]. Several techniques have been attempted to prevent dislocation. Some authors have suggested the use of custom implants, but this proposal has not been widespread in the literature. Blake [18] recommends the use of constrained hybrid prosthesis, consisting of an uncemented acetabular component with acetabular screws, a constrained liner and a cemented femoral component. Some authors suggest routine use of postoperative spica cast immobilization. Transtrochanteric access to the hip can help prevent dislocations because it preserves the integrity of the periarticular musculature and perhaps is a means of reducing motor phenomena as described above.

Other complications included heterotopic ossifications that were noted unless prophylactic nonsteroidal anti-inflammatory drugs are used, this complication occurs after THA in 53% [13] of the patients. Non-union of the greater trochanter is not exceptional. Infections of the implants, with late presentation [15] and with loosening [16], trochanteric Bursitis, and periprosthetic fracture [13, 17]

Hip Fusion

Hip arthrodesis is an option in the treatment of patients with spastic painful dislocation or subluxation of the hip where reconstruction is not possible due to femoral head deformity. Hip fusion is a relatively reasonable option for young, healthy walkers who have unilateral spastic hip disease and no scoliosis. Hip fusion should be considered as an alternative to total hip replacement in young, and functional individuals.

The fusion [19] is performed through a longitudinal lateral hip incision used to expose the hip joint, then capsulotomy is performed and we can observe the deformation of the femoral head and the loss of cartilage. After removing the soft tissue of the acetabulum (ligamentum teres and pulvinar), the articular cartilage is removed, the acetabular cavity is prepared to receive the femoral head. Then the hip is reduced and hip is fixed in the desired position. Usually the implants used to stabilize the arthrodesis are the *cobra head* compression plate, with proximal screws in the iliacus and distal in the proximal femur. After surgery, it is essential to perform regular clinical and radiographic check-ups at least once a year, to monitor the contralateral hip and the spine, especially in more severe patients, to detect any early changes and to treat the deformity before it is severe and fixed (Figure 6).

In 1986 Root [13] reported eight attempted hip fusions. Six of these attempts had a positive result, one needed a repeat procedure to obtain fusion secondary to a pseudarthrosis, and the other was converted to a total hip replacement. Technical aspects were recommended by the author such as the combination of intraarticular and extraarticular arthrodesis, the utilization of muscle pedicle –bone, the use of internal fixation that increases the fusion rate and the femoral osteotomy to correct the femoral anteversion (Root).

Recently Fucs and Cols [19] published a study about 21 patients affected by spastic CP with painful chronic hip subluxation and dislocation treated with hip fusion with a mean

follow-up period of 14.5 years. All patients in this long-term review demonstrated bone union, pain relief, and postural improvement with patient or caregiver satisfaction.

Four patients developed a pseudoarthrosis and needed a repeat procedure to obtain fusion. The final results were considered satisfactory in all patients, although 4 patients needed a second procedure for bone union.

Surgical complications were observed. Root [13] found pseudoarthrosis in two patients, one at eleven months and the other at three years. Both were treated with revision surgery and graft. One patient has supracondylar fracture, another pin intolerance which required pin removal, and two patients had superficial sacral pressure sores.

Figure 6. A. Male patient, age 13+11, spastic diplegic, community ambulator, initial pelvic radiograph. B. Age 29+11, postoperative 17 years of left hip arthrodesis (courtesy Dr. Fucs).

By the other hand, Fucs [19] described no superficial or deep wound infections. One patient's skin was broken in the sacral region due to a pressure sore in the cast period. In another patient an accidental femoral vein laceration occurred during the surgical release of the adductor muscles. This was repaired immediately and there were no further complications. There were 3 patients who presented with femoral fractures following surgery on the side of the arthrodesis.

Both authors concluded that hip arthrodesis is an option for patients with spastic CP with painful subluxation or dislocated hips with the goal of maintaining pain relief or improving functional status, and facilitating care. It is primarily useful if the patient is a young ambulatory with normal contralateral hip and normal spine.

3. COMPLICATIONS OF PALLIATIVE TREATMENT

Among the most significant complications that we can present after palliative surgery we highlight persistent pain and chronic pain syndrome. The continuation of pain after the resection arthroplasty, either the Girdlestone or the Castle procedure, is relatively common, up to 25% of cases. Refractory pain after resection osteotomies resection is frequently described in the literature. Indeed, Widman [7] warns that there may be pain for up to 6 months following the PFRA. Some authors do not recommend new revision surgeries for at least a year.

In cases of interposition arthroplasty or total hip arthroplasty, pain may be secondary to implant loosening or infection. Detailed tests should be performed to determine possible causes of pain. When persistent pain occurs in patients who have undergone surgery for hip fusion the most frequent cause is the non-union of the arthrodesis

It seems reasonable that some of these patients who have long periods of persistent pain may precipitate chronic pain syndrome. Chronic pain in children and adolescents often results in considerable functional disability. Very little has been written regarding chronic pain as a secondary problem in persons who already have a physical disability, despite the potential for pain to increase the negative impact of what may already be a very disabling condition. Functional improvement can be achieved using a multidisciplinary approach to pain management in children.

4. OUTCOMES OF PALLIATIVE SURGERY

Few article in the literature compare different treatments for patients with spastic CP with painful subluxation or dislocated hips. Wright [20] reported a retrospective study which compares the outcomes of 3 different surgical procedures performed at same institution for pain relief in patients with spastic quadriplegic cerebral palsy and painful dislocated hips. The procedures identified were proximal femoral resection arthroplasty (PFRA); subtrochanteric valgus osteotomy (SVO) with femoral head resection; and (3) proximal femur prosthetic interposition arthroplasty (PFIA) using a humeral prosthesis. The outcomes were based on pain and range of motion. Forty-four surgeries in 33 patients, 12 hips were treated with a PFRA, 21 with a SVO, and 11 with a PFIA. An excellent or good result was noted in 67% of PFRAs, 67% of SVOs, and 73% of PFIA. No statistical significance between these procedures was ascertained.

Boldingh and Cols [21] performed a systematic review of the results of palliative hip surgery in severe cerebral palsy. They reviewed articles on resection surgery of the femoral head, arthrodesis of the hip joint, and total hip replacement. They found 44 articles, all of which were observational studies. Finally they found only 8 articles on palliative surgery. The

aspects evaluated were pain relief, seating and nursing problems and complications of the procedures. The published literature does not clearly favor one procedure over the others. The resection arthroplasty technique developed by Castle is reported to yield the best results and fewer complications, and seems to eventually lead to a good outcome.

Graham and Narayanan [1] warn there are many methodological difficulties in measuring the functional outcomes of these procedures. We need improved reporting of pre- and post-operative pain and function, using valid, reliable and responsive outcome measures and health-related quality of life (HRQoL) tools. Although surgical treatment is mandatory in case of painful spastic hip, it is difficult to determine which is the best treatment.

ABSTRACT

One of the goals of cardiovascular surgery is to obtain an optimal hemodynamic state. Cardiovascular surgery often drastically changes the geometric configuration of the heart valve and the structures of vessels; therefore, hemodynamic evaluation has gained popularity among cardiovascular surgeons.

Novel technologies related to imaging modalities are emerging that are capable of estimating blood flow dynamics. Computational fluid dynamics (CFD) has been used since the mid 1990's to reveal the complicated hemodynamics of patients with congenital heart disease. CFD in combination with 3D computer graphics has also been applied in virtual coronary artery bypass surgery. Flow measurement technologies such as 3D cine PC MRI (three-dimensional cine phase contrast magnetic resonance imaging) also known as 4D flow MRI, have recently been applied in patients with chronic aortic dissection or aortic valve disease to determine the optimal therapeutic intervention. Echocardiographic flow visualization has been used to elucidate intraventricular flow patterns after heart-valve replacement.

In this chapter, we summarize the reported hemodynamic evaluation results related to cardiovascular surgery, and introduce novel technologies with potential applications in cardiovascular surgery.

Keywords: computational fluid dynamics, virtual surgery, 3D Cine PC MRI, echocardiography, congenital heart disease, aortic dissection, coronary heart disease

1. HEMODYNAMIC RESEARCH IN THE CARDIOVASCULAR SURGERY

Cardiovascular surgery is performed to avoid life threatening events caused by cardiovascular diseases. Moreover, it is performed to achieve long-term improved cardiac performances for the activities of daily living. Open heart surgery is performed in some patients with complicated congenital heart anomalies to improve cyanosis and ventricular load; heart valve surgery is undertaken to reduce the volume (preload) or pressure (afterload) on the ventricle, coronary artery bypass grafting is practiced to supply sufficient myocardial blood flow and to avoid sudden myocardial infarction, and aortic surgery is undertaken to avoid sudden death. Therefore, the goals of cardiovascular surgery can be said to obtain optimal hemodynamics. Thus, application of hemodynamic research to the cardiovascular surgery is one of the most challenging topics.

Despite recent advances in perioperative patient management, the reduction in morbidity and mortality rate of cardiovascular surgery have been limited; thus, the cardiovascular surgeons should be careful to avoid both oversurgery and mistiming the surgery. Moreover, because switching procedure is difficult after surgery, procedure selection is crucial when planning cardiovascular surgery. Although cardiovascular surgery often drastically alters the shape of the heart valve and vessels and changes the blood flow pathways, its goal is to achieve an optimal and efficient blood flow. However, both the traditional and current surgical indications are primarily dependent on geometric or anatomic information on cardiovascular structures or on the pressure gradient at the site of stenosis. The indications for treating volume overload heart valve disease are based on the size or dimensions of the ventricle; those for treating aortic disease are based on the site of the disease and diameter of the diseased aorta, those for coronary artery bypass surgery are based on the site of stenosis with severity based on the diameter change or pressure drop; and those for treating heart valve stenosis or coractation are based on pressure gradients.

Recently, it has been discussed that a detailed analysis of blood flow is a key to avoiding long-term complications. Observing the disturbed flow, calculating the shear stress exerted on the vessel wall by the blood flow, or calculating the flow energy loss (EL) caused by turbulent flow may permit the reliable prediction of the prognosis of cardiovascular diseases, and may help to evaluate the surgical procedures used to treat them. In this regard, blood flow visualization research results that were depicted by colorful flow streamline, contour distribution of wall shear stress (WSS) on the vessel wall and pressure drop using computer graphics have provided great insight in surgical procedures and their indications. In this chapter, we describe the blood flow visualization techniques suitable for various types of cardiovascular surgeries.

2. METHODOLOGIES IN FLOW EVALUATION

2.1. Overview of Tools for Hemodynamics Evaluation

As described in previous chapters, hemodynamic evaluation examinations include catheter measurements and flow visualization methods based on imaging modalities. Computer flow simulation is another powerful tool for hemodynamics evaluation, particularly

for cardiovascular surgery, because it can predict hemodynamics before performing surgery (Figure 1).

Figure 1. Flow visualization samples using echocardiography, 3D cine PC MRI (three-dimensional cine phase contrast magnetic resonance imaging), and CFD (computational fluid dynamics). These modalities can acquire the distribution of velocity and calculate energy loss. Energy loss based on echography and magnetic resonance imaging (MRI) is calculated based on the disturbance of flow and viscosity, whereas that based on CFD is calculated based on total pressure; however, both are mathematically equal.

Figure 2. The near-wall spatial resolution of each modality. Spatial resolution is defined by sampling size in echography, voxel size in phase contrast magnetic resonance imaging (PC-MRI), and mesh size in CFD. Above: How the region is discretized in each modality. Echocardiography using a sector probe samples the data in polar coordinates. PC-MRI outputs the data in voxels. CFD uses polyhedrons to discretize the space. Below: The size of each sampling are area/voxel/ mesh near the wall in the same scale, showing the effect on the accuracy and precision of wall shear stress calculations.

Table summarizes the characteristics of echocardiography and phase contrast magnetic resonance imaging (PC-MRI) flow visualization modalities and computer flow simulation based on computational fluid dynamics (CFD).

Flow-visualization modalities using echocardiography and MRI are based on actual flow measurements, and are available in daily clinical practice. Nevertheless, they have low resolution and are subject to noise and error, which could cause serious problems when calculating hemodynamic indices essential for the prognosis prediction (Spiegel et al., 2011). Conversely, numerical flow-simulation data based on CFD have sufficiently high resolution without noise.

Table 1. Feature of blood flow visualization modalities

	Echography	MRI	CFD
Labor Hour	10 minute	Few hours	1 day - Few days
2D or 3D	2D	2D and 3D	3D
Wall movement	Possible	Possible	Difficult
Temporal resolution	Coarse e.g. 20 - 30 Hz	Coarse e.g. 7-30 Hz	Fine e.g. 10000-200000 Hz
Spatial resolution	Moderate e.g. 0.1 – 1 mm	Coarse e.g., 1mm – 3mm	Fine e.g. 0.03 mm – 3 mm
Advantage	• Simple and easy. • 3D visualization in vivo • Accurate hemodynamic parameters • Virtual surgery / Simulation under virtual Condition • Analysis using idealized model		
Disadvantage	• 2D Limitation • Coarse resolution • Unclear acquisition protocols • Long acquisition time • Unclear validity • Technical difficulty • Rigid wall assumption		
Typical analysis region	• Ventricle and atrium	• Ventricle and atrium • Large vessel	• Vessel

Table shows an example of the near-wall spatial resolution of each modality. In addition, numerical simulation can be applied to virtual surgery. Using this technique, it is possible to predict blood flow dynamics after surgery, or design new methods of surgery. However, despite the advantages of numerical simulation over other flow measurement modalities, it is technically difficult and time-consuming.

2.2. Hemodynamic Research Using Cardiac Catheterization

Cardiac catheterization is an invasive procedure to investigate the function of the heart. The catheter enters into the blood vessels and allows the direct measurement of the pressure/pressure gradient, measurement of O₂ saturation to evaluate blood flow, or visualization of the blood flow or shape of the cardiac vessels with the assistance of contrast medium. Above all, absolute pressure value measurement cannot be performed by any other

modality. Currently, cardiac catheterization is the gold standard for the diagnosis of coronary artery disease, and congenital heart disease; however, as an invasive examination, it carries the risk of vessel injury or stroke. Catheter angiography provides only 2D images, which can lead to the misinterpretation of complex anatomy (Kern et al., 2010). Pressure measurements by catheter is highly dependent on the characteristics of the flow at the measurement site, such as its direction or turbulence. Regarding its accuracy using a 0.014 mm pressure wire, which is currently considered the gold standard, the procedure demonstrated a 24 % overestimation in peak systolic pressure despite the low catheter vessel radius ratio (De Vecchi et al., 2014). Recently, use of digital measurement wires that simultaneously measure pressure and flow velocity has increased, particularly to evaluate coronary arterial flow, because they provide pressure and flow velocity at the point, they can even provide flow energy loss (EL) based on total pressure (TP) measurements (Honda et al., 2013).

2.3. Hemodynamic Research Using Echocardiography

Flow visualization with echocardiography is noninvasive and portable features that are useful in daily clinical practice for the estimation of myocardium or intraventricular flow. Currently, there are two major groups of flow visualization methods. The first is based on B mode image using contrast medium and is called echo PIV (particle image velocimetry) (Hertzberg et al., 2004), or color Doppler Vector Flow Mapping (VFM) (Itatani et al., 2013, Mehregan et al., 2014). Compared with other flow-visualization techniques, flow visualization using echocardiography is noninvasive and portable and flow analysis can be performed even in patients in intensive care. Further the analysis requires just seconds or minutes. Thus, VFM flow analysis provides an almost real-time flow analysis, even during open heart surgery in operative room based on data acquired using transesophageal echocardiography (TEE). VFM requires a sufficient color Doppler window, which covers the ventricular wall for speckle tracking. Thus, the measurement plane is limited and should be carefully selected. The limitations of flow visualization using echocardiography include a 2D flow assumption and a velocity range far less than the jet flow in valvular diseases. Flow visualization based on color Doppler also has the limitation of aliasing over the Nyquist limit, and the accuracy of echo PIV is considered insufficient with a flow velocity of over 42 cm/s (Prinz et al., 2012); thus, jet flow around the valve or through wall defects cannot be accurately evaluated using this method.

In summary, flow visualization using echocardiography is suitable for daily use because of its portability and rapid analysis. Real-time flow evaluation even during surgery with TEE is possible. Its limitations are 2D flow visualization and a velocity range lower than the jet flow.

2.4. Hemodynamic Research Using MRI (Magnetic Resonance Imaging)

Phase Contrast MRI (PC-MRI) is alternative noninvasive method to visualize blood flow. As other modalities, blood flow is visualized as field of flow vector (Napel et al., 1992), which is called phase velocity mapping (Osinnski et al., 1995). Performing this technique in multislice mode allows the three-dimensional evaluation of blood flow dynamics (Wigström

al. 1996, and 1999), and is called 3D cine PC MRI (also termed 4D flow MRI). It attracts attention because it is the only way to evaluate 3D flow *in vivo*. Thus, it enables the evaluation of blood flow in diseases with a complex 3D geometry such as aortic dissection. As in CFD, the blood flow field is visualized by animation of the 3D streamlines or pathline using 3D computer graphics. In addition, it has the potential to calculate WSS and its fluctuation: termed the oscillatory shear index (OSI) (Barker et al., 2013; Harloff et al., 2010, Papathanasopoulou et al., 2003, Cibis et al., 2014) which are considered important factors in endothelial dysfunction (Reneman et al., 2006).

One of the disadvantages of 3D cine PC MRI is its relatively long data-acquisition time approximately 10 - 30 min, compared with echocardiography or CT (computed tomography). Therefore, eligible patients are limited to those to lie motionless in MRI equipment and who can hold their breath for several seconds. Thus, infants or preschool children are suitable for this modality. Another limitation is its low spatial resolution which affects its ability to estimate the flow in small vessels. The approximate resolution of 3D Cine PC MRI is currently around 1.0 - 3.0 mm, which is not sufficient to evaluate vessels such as the peripheral coronary artery, which is around 2.0 mm in diameter. Furthermore, the low resolution affects the accuracy of WSS calculation (Cibis et al., 2014), even though, it is reported that the WSS distribution is similar to that of numerical simulation in aorta (Boussel et al., 2011). Furthermore, the unclear effects on hemodynamic parameters of data acquisition and processing methods such as spatial resolution or noise reduction are problematic and hinder the clinical applications of flow analysis.

In summary, flow visualization using MRI is useful to understand 3D blood flow in large vessels such as the aorta or in the ventricle. However, the current performance of these MRI machines is insufficient to evaluate small vessels such as the coronary arteries.

2.5. Blood Flow Simulation Using Numerical Models

The zero-dimensional model (Migliavacca et al., 2006) often referred to lumped parameter model (Figure 3), and the one-dimensional model (Hughes et al., 1973) often termed the distributed parameter model are the classical methods of modeling the circulation. These methods use electric circuit units including resistance, inductance and compliance to simulate pressure and flow rate mimicking the vessel function. They are useful tools to simulate the flow and pressure changes after drastic circulatory system changes such as staged palliative changes in single-ventricular physiology in patients with congenital heart disease.

CFD is a fluid flow simulation based on the numerical solution of the *Navier-Stokes* equation (1.17) (1.18) (1.21)-(1.24) using computers. One of its advantages is that it has an extremely high resolution. The temporal and spatial resolutions are determined by the limits of the computer's memory. CFD detects small local flow that can never be measured *in vivo*, and such fine resolution enables precise evaluation of useful parameters such as WSS and EL. Another advantage is that it can simulate various virtual conditions such as exercise by changing flow rate and pressure boundary conditions.

Inlet and outlet boundary conditions, which regulate the flow in the domain, are crucial factors to obtain an accurate result. There are two ways to define boundary condition: first, using measured data, and second, modeling the outside of the boundary. The former is simple

and clear but requires additional measurement data, such as flow or pressure profiles based on Doppler echo or catheter measurements. The latter is powerful to estimate the amount of flow under the conditions of peripheral autoregulation; however, it adds calculation assumptions, and precise parameter settings are necessary to realize physiologic flow.

One of the disadvantages of CFD is that the analysis is a time consuming process. The preprocessing process, with geometry extraction and smoothing, is mainly performed manually and takes a couple of hours, whereas calculation of the *Navier-Stokes* equation for one cardiac cycle of 1.0 second, with a time step size around $50\mu\text{sec}$, a one million element, and using a computer with a 4-6 core 3.5- 4.0 MHz CPU (central processing unit) takes several days. Thus, if surgeons wish to use CFD results preoperatively, elaborate preplanning is necessary.

Figure 3. Boundary conditions using the lumped parameter model (Bove et al. 2008). CFD of Blalock-Taussig shunt using the lumped parameter model as the boundary conditions. The lumped parameter model was used to simulate the whole systemic circuit, coronary circuit, pulmonary circuit, and heart.

Moreover, simulating flow inside moving elastic structures is technically difficult. Fluid Structure Interaction (FSI) refers to simulation that computes both fluid flow and structure deformation. The difficulty of calculating the FSI of the circulatory system is associated with mesh deformation following structure movement. There are several algorithms for mesh deformation, such as the Arbitrary Lagrangian and Eulerian (ALE) and immersed boundary methods; however, in problems with large structure deformations such as heart valve opening/closure, these methods lose their robustness of computation. FSI solves structure equations in addition to fluid equations, not only related to the flow inside or around moving structures, but also related to the stress forces acting on structures including von Mises stress. However, the current cost of FSI is huge (it requires a supercomputer), and current studies on FSI contain too many simplified assumptions about vessel properties, such as uniform elastic

property constants; therefore, their validation is difficult, in vessels with non-uniform structural properties such as atherosclerotic aorta.

CFD can obtain wide-ranging, detailed information on hemodynamics; however, the various manual processes affect the simulation, which could yield inaccurate results. To compute valid results, accurate geometry, appropriate boundary conditions and proper computing algorithms are necessary. Moreover, it is important to compare with actual measurements to confirm the reliability of the CFD method, when planning cardiovascular surgery.

2.6. Computerized Virtual Surgery Based on Computational Fluid Dynamics

Virtual surgery is one of the most useful applications of CFD. It enables the non-invasive prediction of postoperative flow dynamics, and the trial of new surgical methods on a computer (Figure 4).

Figure 4. Computerized virtual surgery on coronary heart disease. Virtual surgery of coronary bypass grafting using computer-aided design (CAD).

Virtual surgery predicts postoperative hemodynamics using post-operative geometry which is generated by deforming the preoperative geometry obtained from patient data. Thus, the modification of geometry plays an important role in computerized virtual surgery. Recently, much sophisticated 3D modeling software for computer graphic has been developed, which offers free and intuitive geometry deformation and/or generation tools. Moreover, 3D computer aided design (CAD) software enables the deformation of geometry with fixed measurements.

Several geometric data description methods for geometry modification are shown in Figure 5. The surface polygon model is fundamental to 3D graphics. The surface of the geometry is described as triangular polygons. Most of the current rendering or 3D engines uses the surface polygon model to depict 3D images. Thus, this format can be used for almost all software, and the data can be transferred between different software. The deformation of the geometry is limited by the topology of the surface triangles. Deformation in uniform polygons causes geometric irregularities; thus, complicated geometry requires file format conversion and other methods. The voxel-based model is a convenient format for complex geometry.

A voxel represents a value on a regular grid in a 3D space in medical images. It is useful because of its ability to deform like clay. Voxel sculpting, which is available in 3D modeling software such as 3D-Coat (Pilgrimage Studio, Ukraine), allows users to deform geometries intuitively without worrying about any topological problem.

Figure 5. Description of the method for 3D geometry. There are several ways to keep geometric data. Left: Voxel format. Most 3D medical data are handled as voxels. Dynamic deformation of the geometry is capable in virtual surgery. Middle: Surface polygon geometry is fundamental to describe 3D geometry. It fits well with the curvature of complex anatomy; however, the deformation is limited by its topology. Right: Idealized solid geometry generated using constructive solid geometry (CSG) method. The geometry is defined using a centerline and diameters.

Thus, it facilitates the virtual deformation of complicated geometry such as a virtual bypass based on the original CT data (Figure 4). Voxel format is not common to all 3D modeling and meshing software, and voxel data should be converted to surface geometry data for transfer to computational mesh creating process.

These two methods are useful for intuitive deformation but have difficulty creating geometry with a precisely defined diameter or curvature. To generate geometry with

reproducibility and precise measurements, constructive solid geometry (CSG), which is commonly used in CAD software, is useful. The CSG method is a solid modeling method that combines simple geometry such as spheres, cuboids, solids of revolution and tubes along spline curves. These simple geometries are united, differenced or multiplied to generate complex geometry. The biggest advantage of this method is that it can define complex geometry precisely using numerical values such as curvature, angle and length, and for these reasons, this method is often used in 3D mechanical CAD software. This method is also useful for generating idealized geometry generated from averaged measurements obtained by angiography excluding individual features. These three methods can be used in combination by exporting or importing data in a common format and combining those using Boolean calculations.

Any complex geometry, whether actual geometry extracted from CT or virtual geometry created on a computer can be generated and edited using these methods, and the flow calculated by CFD. Computerized virtual surgery enables flow analysis of any virtual geometry, even for geometries not realizable in actual human anatomy.

3. APPLICATIONS OF HEMODYNAMIC RESEARCH IN CARDIOVASCULAR SURGERY

3.1. Hemodynamic Evaluation in Surgery for Congenital Heart Diseases

Following surgery for congenital heart disease, hemodynamics changes drastically. Recent advances in perioperative patient management have improved postoperative mortality rates even in patients with complex heart and after neonatal open heart surgery, and the long-term results are gaining attention. Long-term cardiac performance is considered to be associated with hemodynamics, and blood flow analysis is performed especially for palliative procedures in patients with a single-ventricular physiology (Figure 1.28). Particularly, CFD and 3D cine PC MRI have been used to study blood flow after the Fontan (Figure 6).

The Fontan operation is a final palliative procedure in patients with a single ventricle, in which venous blood is connected to the pulmonary arteries (PAs) without passing through the functional right ventricle. After Fontan et al., 1971 reported this procedure, various types of modifications have been reported including total cavopulmonary connections, the lateral tunnel procedure, extracardiac conduits and bifurcated Y-graft modifications, and long-term survival has greatly improved. (Khairy et al., 2008). However, several long-term complications remain, including thrombosis, ventricular failure and sudden death due to arrhythmia. These complications are partly associated with the hemodynamic features of the Fontan circulation in the absence of a functional right ventricle, and flow collision from the superior and inferior vena cava (SVC and IVC) flow. To avoid these complications, low central venous pressure with no flow stagnation is considered to be advantageous, and the anatomical features of Fontan geometry have become a focus of hemodynamic research in this field.

The first CFD Fontan study was performed by Haesdonck et al., 1995 and compared the energetic efficiency of the flow between the APC and cavopulmonary connection. More than

20 studies of Fontan hemodynamics based on CFD have been reported in the past two decades.

Figure 6. Comparison of the visualization of Fontan circulation using CFD and PC MRI (Haggerty et al. 2013). Flow visualization of Fontan circulation. The streamline and hepatic fluid factor (HFD) was compared between CFD and 3D cine PC MRI.

Figure 7. The application of virtual surgery on Fontan patient (Pekkan et al. 2008). Left: Virtual surgery using 6 DoF device enables intuitive deformation of vessel geometry. Right: Patch size is computed from virtual surgery.

There are several important metrics used to analyze postoperative Fontan flow. Flow contribution from the IVC to the left and right lungs is important because a “hepatic factor” is thought to be protective against the development of pulmonary arteriovenous malformations. Patients with left atrial isomerism, such as those with azygous continuations of an interrupted IVC, exhibit this phenomenon. Goksel et al., first described the application of Y-graft Fontan, the conduit of which was from the IVC bearing blood contains the “hepatic factor”, which ensured the equal separation of the IVC flow to the left and right lungs, CFD was used to evaluate the utility of this new surgical method.

Energy efficiency in the Fontan circulation, defined as EL is the outcomes measured by these hemodynamic studies. The reduction in EL based on TP (1.45), (1.A.20), (1.A.21) is used as the index for good hemodynamic performance of the Fontan procedure; also, reduced EL reportedly related to good ventricular diastolic function in the single systemic ventricle after the Fontan procedure. (Honda et al., 2013). Furthermore, the energy efficiency of Fontan hemodynamics is thought to affect the exercise tolerance of patients.

Whitehead et al., 2007 estimated Fontan hemodynamics during exercise using CFD, and concluded that a nonlinear relationship exists between cardiac output and EL, which is highly dependent on the geometry of the TCPC and the division of flow between the left and right PAs. They used the MRI data of 10 patients to generate the geometry and flow rate through the SVC, IVC, and right and left PAs as boundary conditions. The simulation of exercise was performed under the boundary conditions of twice and three times the baseline flow increase of the MRI acquired flow. Haggerty et al., 2013 used both CFD and 3D cine PC MRI to estimate the hemodynamics of 100 patients who underwent the Fontan procedure. They computed Fontan flow using the geometry extracted from MRI and flow rate boundary conditions acquired using 2D PC MRI, and calculated the energy efficiency of patients. Interpreting the EL value is difficult because it varies according to body size, and heart function. Haggerty et al., 2013 normalized EL calling it indexed power loss (iPL) by correcting it for body surface area (BSA) and systemic flow rate (Qs) as in the following equation.

$$iPL = \frac{EL}{\left(\frac{\rho Qs^3}{BSA^2}\right)} \quad (1)$$

iPL is correlated with cardiac index, indicating that high resistance in the TCPC is caused by irregularities in the shape of the PAs, such as narrowing, acute diameter differences, and bending in turn affecting heart function. They also used 3D cine PC MRI to visualize flow in the TCPC to validate the flow computed using CFD, as shown in Figure 6. The computed flow is largely dependent on the boundary conditions, use of a turbulence model, steady/transient scheme and computing mesh quality. Combined use of numerical simulation and actual measurements is useful to compute physiological flow.

Other important hemodynamic information about the Fontan circulation includes flow stagnation, which contributes to the formation of thromboses. In the extracardiac Fontan circulation, SVC conduit size must be selected considering the growth of the patient, and a larger size is preferred. However, the larger the conduit, the more apparent flow stagnation and turbulence become, which could lead to long-term complications such as heart failure or thrombosis. Itatani et al 2009 determined the optimal size of the conduit for the extracardiac Fontan procedure based on energy efficiency and the volume of stagnation. The simulation

was performed based on the idealized geometry generated from the averaged size of angiographic data of 17 patients who underwent the extracardiac Fontan procedure under the transient boundary conditions of flow rate at the SVC and IVC and pressure at the left and right PA outlets which fluctuate with respiration. They concluded that 16 or 18 mm conduits are optimal for children aged 2 - 3 years. In this way, using averaged, idealized geometry for computation is a useful application of CFD that excludes individual differences and can estimate the general tendency of a surgical method.

Recently, CFD has been used not only to evaluate of postoperative hemodynamics but also to predict the postoperative hemodynamic state before surgery. Pekkan et al., 2008 developed the anatomy editing/surgical planning tool (SURGEM) and applied it to Fontan surgery. This software is based on a mathematic model for surface polygon deformation called free-form deformations (FFD) and enables freely intuitive deformation of patient-specific geometry. The deformation is performed using six degrees of freedom (6 DoF: 3 axis position and 3 axis rotation) trackers to control the parameters of FFD (Figure 7). Even though its deformation does not solve stress on the vessel, 6 DoF device and FFD enable pulling, pushing and twisting of the geometry vessels with simple and natural gestures of both hands.

There are several limitations of Fontan CFD studies. Many Fontan CFD studies use steady-state computation, and few compute pulsatile flow. However, regarding the fluctuation of flow in the Fontan circulation, the fluctuation caused by respiration is more dominant than that caused by heartbeat; in fluctuation caused by respiration, the lung sucks in blood flow as a result of a pressure drop in the Pas following expiration. This mechanism is called respiratory pump and is a power source of the Fontan circulation (Hsia et al., 2000). Although the respiratory pump regarded as an important factor in the Fontan circulation, few previous CFD simulations consider this mechanism in their boundary conditions. Therefore, Fontan CFD has the longest history in the applications of CFD in cardiovascular diseases; however, the method of computation, mainly regarding boundary conditions, is not completely established. For this reason, the combined use of numerical simulation and actual measurements such as those obtained using 3D cine PC MRI is important for the validation of the CFD flow analysis system.

3.2. Flow Evaluation in Coronary Artery Bypass Grafting (CABG)

Coronary heart disease is one of the most common cardiovascular diseases in elderly people. Angina pectoris or myocardial infarction is caused by the interruption of blood flow in the lumen of coronary arteries narrowed by the buildup of plaques along the inner wall. The current method of diagnosing coronary heart disease is based on function and morphology. Fractional flow reserve (FFR), Doppler wire assessment coronary flow reserve (CFR), and scintigraphy are proven techniques for functional evaluation. However, these catheter based measurement are invasive, and scintigraphy may underestimate severe multivessel disease. Regarding the evaluation of morphology, coronary angiography (CAG), coronary CT, and intravascular ultrasound (IVUS) are used to estimate the amount and vulnerability of the plaques, and the severity of the stenosis. The gold standard is CAG; however, it could underestimate the severity of stenotic lesion in arteries with complex irregularity or tortuous course (Kern et al., 2010).

Flow analysis is beneficial because the goal of treatments for coronary artery disease is sufficient blood flow to the myocardium. CFD is the only tool currently available to obtain a detailed picture of flow dynamics at diseased sites in the coronary artery; because the resolution of MRI and echocardiography is too low to detect detailed flow inside small coronary arteries. Recently, a technique called computation of fractional flow reserve from coronary computed tomography angiography (FFR_{CT}) was demonstrated to be capable of calculating FFR using CFD (Kim et al., 2010), and the FFR calculated correlated with actual measurement obtained by catheter (Koo et al., 2011). Based on its clinical utility, Heart Flow Inc. the first commercial application of CFD for clinical use was developed for the evaluation of ischemic heart disease with the advantages of reduced cost and noninvasiveness.

The advantages of the application of CFD for the assessment of coronary heart disease are not only the noninvasive FFR evaluation, but also that the technique can estimate stress on the intimal wall of coronary arteries, which may predict the progression or rupture of plaques. WSS and its fluctuation in the cardiac cycle termed oscillatory shear index (OSI) are thought to be important factors because they promote plaque progression or to elevate free radical levels in endothelial cells. (Samady et al., 2011, Harrison et al., 2003, Chatzizisis et al., 2007). Because WSS is calculated from a spatial differential of velocity, and because the size of coronary arteries is small at approximately 3 mm in diameter, it is very difficult to obtain actual measurements for WSS; thus, CFD, which can visualize flow at extremely high resolution, is the most useful and reliable modality to evaluate stress. The small diameter of the coronary artery also cause problem with actual measurement by catheter. Catheter which are 0.014 mm in diameter with a circular cross-sectional shape have a large resistance for blood flow, and are known to disturb arterial flow. Tori et al., 2007 studied the effect on flow of a catheter in an idealized model of a coronary artery with a diameter of 3 mm, and found that the presence of the catheter altered the flow patterns and increased the pressure drop. In addition, velocity measurements were underestimated during one cardiac cycle.

CFD is also useful when planning a surgical strategy for the treatment of coronary heart disease. Coronary artery bypass grafting (CABG) is commonly performed in coronary arteries with stenotic lesions to restore blood flow. The success of CABG is dependent on the long-term patency of the arterial and venous grafts, which is in turn dependent on the design of the coronary revascularization. However, the optimal bypass design is uncertain especially, particularly in cases with multivessel disease, because of flow competition between the graft and native vessels (Nakajima et al., 2007). Using virtual surgery, the shape of the CABG can be optimized to achieve an adequate flow rate and long-term patency. Dur et al., 2011 developed a surgical planning method using a combination of computer-aided design (CAD) and CFD. This method models the whole anatomy of the patient-specific aortic arch and coronary arteries and uses the lumped parameter model as the boundary conditions. Each outlet has resistance for the outlet boundary conditions. Virtual grafts are added to the 3D geometry generated from preoperative patient data, such as CT and MRI data using an in-house anatomic editing tool based on solid modeling. This system also provides automatic optimization of the graft shape based on the CFD evaluation of the cost function.

The optimization is performed in 2D CFD using the 2D projected geometry of the virtual graft. The shape of the graft, including the angle of anastomosis and curvature vectors of the proximal and distal portions is determined according to the cost function that evaluate the velocity gradient, pressure drop, mean WSS, flow deviation angle, and vorticity. Once the optimized 2D geometry is generated, it is converted into 3D geometry and 3D CFD is

performed using the geometry. This system is unique in that it divides the CFD process into two stages: first, 2D CFD, which has an adequately low computational cost, enabling a large number of iterations for optimization of the graft shape; and second, 3D CFD, which enables a detailed hemodynamic evaluation of the whole anatomy of the coronary arteries and grafts. The optimal bypass root is automatically defined with a practical computational cost.

Figure 8. Idealized geometry CFD on coronary heart disease (Koyama et al 2014). Left: Coronary artery geometry was generated using solid modeling based on patients' average measurements. The general tendency of the flow was evaluated by comparing different bypass models. Right: The pressure distribution and streamline colored by origin of flow was visualized in several phases.

In addition to estimating patient specific hemodynamics, CFD also enables the evaluation of the general tendency of surgical methods. Koyama et al. 2014 used idealized coronary artery geometry to estimate the optimal bypass design for CABG for the left anterior descending and diagonal coronary arteries based on CFD idealized geometry created by using 3D mechanical CAD software as shown in Figure 8. They created a coronary artery model that reflected geometric features of coronary artery branches that include vessel diameter and the angles of the averaged data of 10 normal individuals. They revealed that the combination of graft design and the severity of native coronary stenosis affected the flow in each branch: reverse flow in the grafted vessels sometimes created disadvantageous flow collision; however, in some situations it acted as additional flow to another grafted vessel. (Figure 9). Patient-specific CFD is a substitute for actual measurements that can obtain much detailed information on blood flow less invasively. To estimate general tendencies using a patient-specific model, statistical analysis based on CFD calculations in a large cohort is necessary, which requires a lot of time and effort. However, CFD using idealized geometry can evaluate

general tendencies in only one analysis. Moreover, it is easy to perform controlled experiments using an idealized model by independently modifying the flow rate/pressure boundary conditions.

Figure 9. Two types of idealized coronary artery bypass model were created, and the impact of the top-end anastomosis design on patency and flow stability were evaluated based on wall shear stress (WSS) and oscillatory shear index (OSI) (Koyama et al. 2015). Model A: The top-end anastomosis is parallel to the long axis of the ascending aorta and the graft passes over the right ventricle. Model B: The top-end anastomosis is directed toward the shortest pathway, and forms at nearly a right angle to the long axis of the ascending aorta.

3.3. Prediction of the Prognosis of Aortic Disease

Ruptured aortic aneurysm is a life-threatening disease. There are no effective medications or therapies for aortic aneurysms, most patients postpone treatment until their aneurysm is enlarged. The indications for the surgical treatment of aortic aneurysms are determined based on their diameter (Brewster et al., 2003). However, predicting the progress of aneurysms is

difficult and rupture can occur even if the diameter is under the threshold (Davies et al., 2002, Dapunt et al., 1994). Several studies on features such as the geometry of the aortic curvature and mechanical properties of the aorta (Elefteriades et al., 2010, Poullis et al., 2008, and Koullias et al., 2005) have attempted to establish alternative criteria for the diagnosis of aortic aneurysm.

Several recent studies using numerical analysis have reported a relationship between hemodynamic parameters and rupture risk. Fillinger et al., 2002 studied differences in peak wall mechanical stress in patients with abdominal aortic aneurysm (AAA), and found that peak wall stress was significantly higher in the ruptured group (Fillinger et al., 2002). Truijers et al 2007 reported that AAA wall stress at peak systolic pressure was significantly higher in ruptured than asymptomatic aneurysms. In a patient-specific analysis, it is important to derive the accurate geometry of the lumen, thrombus, wall and calcifications: thrombi decrease wall stress, whereas calcifications increase the stress. They referred that geometry of lumen and calcifications can be obtained using 3D CTA or MRI; however, that of thrombi and the wall thickness is more difficult to derive because the boundary between thrombi and the wall is unclear. Thubrikar et al., 2001 showed that a wall thickness increase from 1.31 to 1.58 mm results in an increase in stress of up to 21 %. Xenos et al., 2011 emphasized the importance of advanced material properties for performing a reliable stress analysis (Figure 10): An anisotropic material model predicted higher principal axis stress than an isotropic material model. These studies, which use seismic analysis without considering the effect of fluid forces, can be performed to estimate mechanical wall stress based on the finite element method; however, several previous studies have shown that the influence of fluid force on wall stress is up to 25 % (Papaharilaou et al., 2007, Scotti et al., 2008). FSI enables a more detailed prediction in the interaction between aneurysmal wall and blood flow there. For example, a large iliac angle reportedly increases the von Mises stress in an AAA. Also, it was demonstrated that the use of FSI permitted the prediction of the location of rupture in several cases of ruptured AAA (Xenos et al., 2011). However, the FSI requires too much time and effort to perform on each patients, and it is difficult to examine in a large cohort study.

In addition to a rupture risk analysis, CFD flow analysis has been applied to predict aneurysm progression. 3D cine PC MRI (4D flow MRI) has also been used to assess the risk of progression of aneurysms. Although 4D flow MRI cannot provide information on the pressure inside the lumen or von Mises stress on the wall, WSS and OSI can be calculated and they are believed to play an important role in the prediction of aneurysm progression (Biegging et al., 2011, Boussel et al., 2011). The coarse spatial resolution of MRI is disadvantageous in the calculation of WSS, nevertheless, WSS derived using MRI is reportedly concordant with CFD results (Boussel et al., 2011) and other measurement studies (Bürk et al., 2012). Currently, there is insufficient evidence on these parameters because of a lack of follow-up.

Aortic dissection is one of the most catastrophic diseases in cardiovascular disease with a mortality rate increasing 1-2% per hour after symptom onset. It is classified into two types, Stanford Type A and B depending on the dissection site.

Stanford Type A aortic dissection, which involves the ascending aorta, requires primary surgical treatment. Stanford Type B aortic dissection, which does not involve the ascending aorta, is generally treated with medication as the initial treatment, and the majority of patients with Type B dissection survive the acute phase. However, the long-term prognosis is not always sufficient: the dissection develops aneurysmal dilatation within 1-5 years in

approximately 20-50% of patients (Khan et al 2002), which is considered a significant predictor of poor survival (Genoni et al., 2002). Recently, the relationship between the prognosis of patients with Type B dissection and blood flow abnormalities has been discussed. For example, it is known that patients with thrombosis of the false lumen have an improved outcome, whereas those with a patent false lumen have an increased risk of aortic expansion and death (Bernard et al., 2001, Pretre et al., 1997), and that flow abnormalities and stasis are factors that contribute to thrombus formation. Additionally, recent studies using computer simulations have shown that abnormal flow patterns in the dissected aorta play a role in false lumen expansion and aneurysm formation (Cheng et al., 2010).

Figure 10. Analysis of stress on abdominal aorta aneurysm (AAA) using fluid structure interaction (FSI) analysis (Xenos et al. 2011). Fluid-structure interaction analysis of an abdominal aortic aneurysm. Thrombus decreases the von Mises stress on the wall, while calcification increase this stress.

Computational simulation and 3D cine PC MRI are the commonly-used modalities for flow evaluation of the dissected aorta. Computer simulation is capable of calculating hemodynamic parameters, including WSS and OSI, considered to have a key role in the development of aneurysms (Bürk et al., 2012). However, because computational simulation is dependent on the assumptions including medical image information, it is important to identify the entry and re-entry that dominates flow in the false lumen. Karmonik et al., 2011 simulated the hemodynamic effects of entry- and exit-tear coverage in a Type B dissection using CFD based on 4 geometries that differ in terms of entry and re-entry tears as shown in Figure 11.

Figure 11. CFD analysis in aortic dissection (Karmonik et al. 2011). The existence of entry and re-entry was virtually changed: #1: Geometry at presentation, one entrance and one exit tear. #2: The exit tear was virtually removed, simulating thrombotic occlusion of the exit tear during disease progression. #3: The entrance tear virtually occluded mimicking endovascular intervention. #4: The flap was virtually removed, simulating surgical fenestration.

They found large variability in pressure and velocity in the false lumen pressures in 4 scenarios, and that the outflow restrictions may cause elevated false lumen pressures, promoting lumen expansion. Their results had the limitation that the information on entry or re-entry tears, despite the low spatial resolution, could greatly affect the calculated results.

One of the difficulty in CFD modeling of the dissected aorta is the control of movements in the dissected flap. The flaps dynamically move by the pressure difference between the true lumen and the false lumen, changing the shape and volume of the pathway of blood flow, and simple rigid flap assumption is unsuitable in these problems. However, there are several technical difficulty in modeling with FSI such as elastic property distribution in addition to the vast calculation costs.

3D cine PC MRI is useful to analyze the flow in patients with complex 3D anatomy, such as aortic dissection. The aorta has adequately large that even the low spatial resolution of MRI is considered to have a small effect on the flow measured. Clough et al., 2012 analyzed hemodynamics in dissected aorta of 12 patients with Stanford Type B by aortic dissection using 3D cine PC MRI (Figure 12), and found that relationships exist between the position of the dominant entry tear and the area of greatest false lumen expansion, and between the position of distal entry tears and the aortic expansion. François et al., 2012 analyzed hemodynamics in the true and the false lumina of 12 patients using 3D cine PC MRI, and visualized and analyzed the differences between flow in the false lumen and that in the true lumen. According to this study, the flow velocity in the false lumen is lower than that of true lumen, and flow reverse in systolic phase was observed in false lumen of some patients,

which thought to be caused by pulse wave reflection from the distal end of a false lumen with no re-entry. In addition, abnormal flow, including vortex flow, was observed in both the true and false lumina, which is thought to be caused by the moving flap.

Figure 12. Flow analysis in a dissected aorta using 3D cine PC MRI (Clough et al. 2012). Identification and quantification of helical flow using 3D cine PC MRI. Helicity (degree/s) was quantified based on the amount of rotation in the plane shown in C.

Although 3D cine PC MRI is suited to the analysis of aortic dissection, research results obtained with 3D cine PC MRI related to the aortic dissection are only just being reported. Several technical limitations including the data acquisition process and post-processing, must be overcome to perform high volume multicenter studies. Thus, there is no statistical evidence regarding the hemodynamics of the dissected aorta. Larger prospective studies are required to determine a method of the prognosis of aortic dissection using 3D cine PC MRI.

3.4. Applications in Valve Surgery

Patients with heart-valve insufficiency or stenosis are typically evaluated by measurements of flow and/or pressure. The severity of aortic valve stenosis is classified into 3 groups according to the measured flow and pressure (Zoghbi et al., 2003). However, the primary indication for intervention is often symptom development (Vahanian et al., 2012). For early treatment, more reliable parameters for valvular heart disease are required. Currently, the transvalvular pressure gradient is the commonly-used parameter for the determination of treatment indication. However, several previous studies have emphasized the importance of pressure recovery that occurs on downstream of heart valves (Baumgartner et

al., 1990). Flow EL is well-established concept that evaluates not only pressure loss but also kinetic EL. Some studies have this parameter to evaluate heart valve performance. Bahlmann et al., 2013 reported the difference in survival rate between patients with aortic stenosis. It was also reported that EL in patients with dilated cardiomyopathy decreases with a decrease in size of the vortex after medication (Nabeta et al., 2014). Recently, Itatani et al., 2014 reported a method to evaluate EL based on viscosity and blood flow vector distribution. Using this method, EL can be calculated without pressure information, which enables EL evaluation using VFM and 3D cine PC MRI. Local EL is calculated and depicted as shown in Figure 1. It is useful to know the cause of the loss, and to interpret the variety of vortex flows formed in the ventricle/vessel. For example, Figure 14 shows the velocity and flow streamlines with vorticity after mitral valve replacement.

Figure 13. The intraventricular vortex after mitral valve surgery (Modified image from Itatani K. 2014).

Each case shows different-shaped vortices which are not seen in the normal ventricle. In the case of a mechanical valve fitted in an anti-anatomic position, transmitral flow collides with the antero-septal wall, and, is directed to the apical and posterolateral walls, forming a large vortex filling the whole ventricle. In a case after mitral valve plasty, left ventricular vortex flow appeared as a physiological flow pattern with a large clockwise vortex. Conversely, in case of a mechanical valve fitted in an anatomical valve position and in a case of mitral valve plasty, transmitral flow formed a clockwise vortex as normal. These abnormal flow patterns have the possibility to decrease the efficiency of the flow and increase the EL. This information is useful when considering a treatment plan.

However, VFM has the limitation of 2D measurement. In some cases, disturbed flow or jet flow may not fit inside the single plane of echocardiography, which may lead to the underestimation of EL. Currently, the only way to visualize 3D in-vivo flow in actual measurements is using MRI. It is capable of calculating the EL of the disease (Barker et al., 2013). However, noise in the velocity distribution is problematic when calculating EL. As

shown in Figure 14 noise largely affects the EL. Thus, MRI data-acquisition conditions and noise reduction in post-processing directly change the EL value. Validation studies on spatial resolution and noise reduction, as well as clinical studies are required to examine these issues further.

Figure 14. The impact of noise on energy loss calculation. Flow visualization using 2D phase-contrast MRI. Left: The visualization of flow and energy loss without the smoothing of velocity. Middle: Gaussian smoothing with 3 pixel standard deviation. Right: Gaussian smoothing with 6 pixel standard deviation. Energy loss is largely dependent on the noise in velocity distribution.

The computational simulation method has also been studied in some groups. Drastic movement of the valve makes it difficult to simulate on a computer because of the difficulty of computing mesh deformation. Katayama et al., 2013 developed an automatic mesh reconnecting algorithm to avoid this problem. They simulated blood flow and the motion of the aortic valve leaflets using FSI to examine the influence of the morphologic characteristics of the bicuspid aortic valve on disease progression by comparing the motion, stress/strain distribution, and blood flow of normal and stenotic tricuspid valves. They found that the characteristic morphology of the bicuspid valve creates excessive bending strain on the leaflets during ventricular ejection, and a greater increase was observed in the bicuspid valve. Valve analysis based on computer simulation is technically difficult because of mesh torsion caused by large movements of the aortic valve, and few studies have been conducted. However, numerical simulation enables the gathering of high resolution information about

valve movement and an understanding of the surrounding hemodynamics, which cannot be observed using actual measurements, can be obtained by numerical simulation.

FUTURE PERSPECTIVES AND CONCLUSIONS

Flow visualization enables the calculation of various hemodynamic parameters, which presents predictive indicators for the progression of cardiovascular diseases. These parameters and the visualized flow are helpful to understand the complex flow dynamics of cardiovascular diseases, which is in turn helpful for surgical planning. There are several modalities of flow visualization and each has advantages and disadvantages. The appropriate modality must be selected according to its purpose and the region for analysis. CFD is useful in virtual surgery, idealized geometry analysis and for small vessels. 3D cine PC MRI is useful in regions where structures have a large impact on blood flow such as around the valves and in the ventricle. Furthermore, it is useful to evaluate complex 3D flow. Echocardiography is simple and the time required for analysis is short, which is useful for routine clinical use.

Currently, clinical evidence for the utility of blood flow visualization is scarce because of a lack of large cohort studies. However, systems for analyzing blood flow have undergone rapidly development recently, and flow analysis will become the standard for the diagnosis of cardiovascular diseases.

Flow visualization using echocardiography is a powerful tool to evaluate the intraventricular blood flow; however, evaluation in 2D measurement plane is a big limitation especially in turbulent flow in valvular heart disease. In future, this kind of modality should be aiming toward 3D flow evaluation using 3D echocardiography. MRI is a powerful tool because it can acquire 3D flow distribution in actual measurement. This advantage is beneficial in evaluating the flow in the complex structure such as aortic dissection whose flap drastically moves in a cardiac cycle. Currently, target of MRI is limited to large vessel, but performance of MRI machine continues to improve with the development of technology; thus, small vessel flow will possibly be evaluated in future. The use of computational simulations will be much focus on virtual surgery combined with computer graphics or study based on idealized model to conclude general information such as indication of surgical treatment.

Chapter 365

TRANSFUSION PRACTICES IN CARDIAC SURGERY

***Surendra Kumar Agarwal**, *Gauranga Majumdar*,
*Shantanu Pande and Siddhartha Churchigundi Rudrappa***

Department of CVTS, SGPGIMS, Lucknow, India

ABSTRACT

Cardiac surgery is the main source of consumption of majority of blood products, and best practices are required to reduce the use of this scarce resource. Use of blood and blood products is also associated with increased morbidity and mortality in cardiac surgical patients. This should aim at reducing risks associated with transfusion while at the same time correcting anemia and reducing bleeding. Transfusion-related lung injury is an important complication associated with blood and products transfusion in cardiac surgery patients. The methods to achieve optimal utilization of blood products in cardiac surgery include preoperative, intraoperative as well as postoperative measures. Preoperative identification of risk factors using proper transfusion triggers and development of Maximum Blood Ordering Schedule (MSBOS) for various procedures in the hospital and judicious use/stoppage of medications help reduce bleeding associated with cardiac surgery. Intraoperative use of antifibrinolytic and other medications results in reduction of bleeding and transfusion requirements. Use of minimal invasive procedures, modifications in cardio-pulmonary bypass circuits, and various modes of salvage of shed mediastinal blood during the surgical procedure have been shown to reduce transfusion requirements. Autologous donation, both preoperatively along with erythropoietin (EPO) therapy and intraoperatively, just before going on cardiopulmonary bypass (CPB) may also be used in the select group of patients. Various types of hemostatic agents are used to reduce bleeding and need of transfusion and include topical agents used in the surgical field as well as systemic agents such as factor concentrates. In the postoperative period, use of positive end expiratory pressure and salvage of shed mediastinal blood are helpful in reducing use of blood products. There are special situations, which require specific management. These include hypothermia during surgery and issues related to cold agglutinins, special issues in cyanotic congenital heart disease patients, and management of heparin and protamine during CPB. Heparin resistance and heparin-induced thrombocytopenia also pose important challenge during

* Corresponding Author's Email:surendra2000_in@yahoo.com.

cardiac surgery and need special attention for diagnosis and management. Recent developments include use of various point-of-care devices for targeted management of heparin and protamine. These devices are also helpful in specific management of bleeding by diagnosing the deficiency of specific factors in a particular patient and using the required blood products. A team approach involving surgeon, anesthesiologist, perfusionist, transfusion medicine specialist, ICU care providers, cardiologists, nurses, and other personnel involved in care of patient undergoing cardiovascular surgery is required. This multidisciplinary team approach will be helpful in risk assessment, development, and use of best practice guidelines for transfusion for the institution. A rational use of various methods for individual patients will result in the best outcome at a reasonable cost.

Keywords: cardiac surgery, transfusion, hemostasis, point of care devices, cardiopulmonary bypass, transfusion triggers

INTRODUCTION

Cardiac surgical procedures account for 14–20% of the use of blood and blood products' pool available. [1–3] As blood is a scarce resource, it is imperative to adhere to best practices for transfusion and evidence-based strategies for reduction in use of blood and blood products in cardiac surgery. This is more important in view of the fact that most of the consumption of blood products in cardiac surgery is by a minority of patients [4] and also that transfusion is associated with an increase in morbidity and mortality. [4] The need of transfusion in cardiac surgery is required to correct anemia (red cells) and control non-surgical bleeding (blood products such as plasma, platelets, etc.). Acute anemia results in reduced oxygen delivery and tissue hypoxia, which may cause organ failure and death. The heart extracts 60–70% of delivered oxygen under normal conditions and therefore the only compensatory mechanism available to the heart for increasing oxygen delivery is to increase blood flow to myocardium through coronary vasodilatation. This is difficult in patients with coronary artery disease and myocardial hypertrophy, aortic valve disease, and other conditions. [5, 6] Acute hemodilution during cardiopulmonary bypass (CPB), along with non-physiological non-pulsatile flow results in increased risk of stroke, [7, 8] renal dysfunction, [9] and other organ dysfunction. [10] A retrospective study of 1188 adults undergoing cardiac surgery under CPB found that excessive postoperative bleeding was associated with increased risk of re-exploration for bleeding, stroke, prolonged ventilation time, and intensive care unit (ICU) stay and 30 day mortality. [11] Excessive bleeding also resulted in significantly increased cost.

RISKS ASSOCIATED WITH TRANSFUSION IN CARDIAC SURGERY

Most important and feared risk of blood transfusion is transmission of infections (human immunodeficiency virus, hepatitis B, hepatitis C and other viral, bacterial, and parasitic infections). [12–14] Although rare, [15] the risks are real in countries like India where modern blood banking practices are often not available and because of paid donors who

masquerade as relatives. The other problems include immunological reactions (febrile non-hemolytic transfusion reactions, anaphylactic reactions, ABO mismatch, hemolysis, leukocyte-related organ injury, post-transfusion purpura, acute lung injury (ALI), and sometimes death), screening-related errors like malaria, Creutzfeldt–Jacob disease, and other related disease transmission and mismatch-related errors. [4] Many studies in recent years have shown that allogeneic blood transfusion, especially with blood which has been stored for longer period, is an independent risk factor for increased morbidity as well as mortality including increased hospital stay and costs. [16–19] Although some of these results might have been associated with confounding bias of the inclusion, they cannot be ignored. Exact reasons for this are still unknown, but one of the causes of perioperative mortality in these patients has been ALI following blood transfusion.

Transfusion-Related Acute Lung Injury

Phillips and Fleischner described three patients with transient non-cardiogenic pulmonary edema along with fever, cough, and cyanosis following blood transfusion in 1966. [20] This reaction was initially termed pulmonary hypersensitivity reaction. In 1985, Popovsky and Moore described similar reaction in 36 cases and termed it transfusion-related acute lung injury (TRALI). [21] The entity was being recognized more and more commonly and in 2006, more than 50% of deaths related to transfusion were attributed to TRALI. [22] TRALI is defined as ALI, occurring within 6 h of transfusion of one or more plasma containing blood/blood products in patients without pre-existing risk factors for ALI or in patients with risk factors for ALI if ALI was not present before transfusion or if there is a temporal association between transfusion and ALI. ALI is defined as $\text{PaO}_2/\text{FiO}_2 < 300$ mmHg or $\text{SpO}_2 < 90\%$ on room air, clinical features of hypoxia and bilateral infiltrates on chest X-ray in the absence of increased left atrial pressure. [23] The pathophysiology of TRALI is being understood and is considered to be due to leukocyte antibodies present in donor blood. [24] TRALI is associated with 5–13% mortality. [25] Recent guidelines by the International Society for Blood Transfusion (ISBT) recommend screening of high-risk donors (parous women and individuals who have undergone transplantation and transfusions) for leukocyte antibodies for prevention of TRALI. [26] TRALI is more common in patients undergoing cardiac surgery. This may be due to additional inflammatory response to CPB, both systemic as well as pulmonary. [27, 28]

Risk Factors for Transfusion in Cardiac Surgery

Studies in the Society of Thoracic Surgeons (STS) Adult Cardiac Surgery database has revealed that only about 50% of patients undergoing cardiac surgery need blood transfusion [29] and patients receiving over 10 units of blood products fall in the 90th percentile of the patient transfusion profile. [4] This suggests that some patients are at a higher risk of bleeding or need blood transfusion after cardiac surgery. Preoperative recognition of these risk factors and appropriate intervention at various stages will help in minimizing the blood transfusion requirements. The 2007 STS guidelines on blood conservation [4] suggested three major risk factors: advanced age, decreased red blood cell volume before surgery due to anemia or

smaller body size, and complex or emergency surgeries like re-operations, aortic surgery, and non-coronary bypass grafting (CABG) operations. Table 1 gives a list of various risk factors associated with need for blood transfusion after cardiac surgery. Various studies, both observational as well as with multivariate analysis, have identified predictors of bleeding and blood transfusion after cardiac surgery but odds ratios are available in only a few reports. Although some of risk factors may be a spectrum of low to high intensity, it is not quantified by any robust study till date. Unfortunately, review of available literature failed to give a reliable method of assigning relative values to various risk factors or to provide evidence to stratify various interventions for blood conservation by risk factors. [30] Presence of these risk factors, especially those undergoing complex surgical procedures like combined valve and CABG, aortic surgery and surgical procedures requiring deep hypothermic circulatory arrest etc. should act as “red flag”, and adequate measures should be taken for blood conservation in these patients.

Table 1. Factors that increase bleeding and use of blood products in cardiac surgery

Patient-related factors	Procedure related	Surgeon/unit related
Advanced age, especially >70 years	Prolonged cardio-pulmonary bypass time	Non-use of algorithm for transfusion
Female gender	Reoperation	Non-use of point of care testing
Smaller body surface area	Complex procedure (aortic surgery, combined valve, coronary procedure, etc.)	Use of bi-lateral internal mammary artery
Preoperative antithrombotic therapy (oral anticoagulants, unfractionated heparin, low molecular weight heparin, short- or long-acting direct thrombin inhibitors)	Increased dose of protamine after bypass to neutralize heparin	Use of lower dose of heparin
Preoperative use of low intensity antiplatelet agents (aspirin, clopidogrel, dipyridamole, tirofiban, etc.)	Increased volume in cell saver	Lower body temperature while the patient is in ICU
Preoperative use of high intensity antiplatelet therapy (abciximab, etc.)	Intraoperative autologous donation	
Preoperative thrombolysis	Need for transfusion during CPB	
Hereditary coagulopathy or platelet function disorders ^a von-Willebrand's disease, Hermansky–Pudlak syndrome, Bernard–Soulier syndrome, Glanzmann's syndrome, hemophilia, deficiency of clotting factors, etc.	Use of polymerized starch as volume replacement	
Acquired coagulopathy or platelet dysfunction (cirrhosis, polycythemia vera, chronic lymphoid leukemia, myelodysplastic syndrome, idiopathic thrombocytopenic purpura, thalassemia, etc.)		
Cardiogenic shock		
Congestive heart failure		
Renal dysfunction		
Liver dysfunction		
Adult onset insulin dependent diabetes		
Preoperative sepsis		
Peripheral vascular disease		

Patient-Related Factors

Thrombocytopenia (platelet count <50,000/cmm) [31–35] or thrombasthenia [4] (qualitative defect in platelet function) from any cause (Congenital viz. Von-Willebrand's disease, Bernard–Soulier syndrome, storage pool disease and acquired viz. liver disease, renal disease and drug induced) and hyper-responsivity to aspirin in association to preoperative use of antiplatelet agents, [36] which usually results from pharmacogenetics involving antiplatelet, anticoagulant, anti-inflammatory, and endothelial protecting properties of these drugs predisposes patients to increased risk of bleeding. [4] Anemia due to any cause also results in increased risk of transfusion, [37] and this risk is increased by antiplatelet drugs. [36]

Surgeon-Related Factors

Apart from transfusion practices used by a particular surgeon/unit [2] including triggers for transfusion (symptom based vs. based on level of hemoglobin), [38] variations in CPB practices, CPB time, use of hypothermia [39] and management practices for post-operative bleeding [40, 41] are important determinants of transfusion.

Procedure-Related Factors

Although surgery- and surgeon-related factors are usually inter-related, certain procedures are at unusually high risk of bleeding during and after cardiac surgery and in turn usage of blood products. These include but not limited to re-do surgical procedures, [42] use of CPB vs. Off-pump surgery, [43] use of bilateral mammary artery vs. use of saphenous veins for CABG, [44] Ross procedure [45] (replacement of aortic valve with pulmonary autograft), use of ventricular assist devices (VAD), and artificial heart [46–48] and aortic surgery.

INDICATION OF TRANSFUSION IN CARDIAC SURGERY

The basic indications for use of blood products in cardiac surgery remain correction of anemia and oxygen carrying capacity of blood and correction of coagulopathies. At this point of time, objective evidence is lacking regarding these decisions. Development of “transfusion trigger” which is a level of hemoglobin, hematocrit for red blood cell transfusion, and value of platelet count for platelet transfusion. Initially, hemoglobin level of <10 g/dL or hematocrit value of <30% was used as a trigger. However, there is no evidence supporting this practice. Similarly, there is no evidence for use of estimation of intravascular blood volume or blood loss for transfusion decisions. Measurement of oxygen consumption, whole body oxygen carrying capacity, oxygen extraction ratios, and oxygen delivery [49] may provide a better method to determine need of red cell transfusion, but these measurements are not routinely available and may not be cost-effective. The physiological threshold at which insufficient

oxygen delivery starts decreasing oxygen consumption in human beings is a hemoglobin level of <5 g/dL, oxygen extraction ratio of <0.44, mixed venous oxygen of <34 mmHg, and mixed venous saturation of <56% [50] and may be an absolute indication/trigger for red cell transfusion. But, in cardiac surgical patients, various factors such as coronary artery blood flow reserve and myocardial hypertrophy compound the situation and these patients may not tolerate these low values. A study [51] did not find any increase in mortality in cardiac surgery patients till perioperative hemoglobin fell below 5 g/dL. A group of patients, Jehovah's witnesses, refuse any blood/product transfusion and have provided some data on this issue. A review of literature of studies between 1983 and 1990, involving over 1000 patients concluded that anemia and lack of transfusion influenced mortality only in 1.4% patients in this group, [52] which was also confirmed in a later review of over 4000 patients. [53]

Various organizations such as National Institute of Health, American Association of Blood Banks, American College of Physicians, and American Society of Anaesthesiology convened consensus meetings and task forces and reviewed literature extensively and published guidelines for evidence-based use of red cells, platelets, fresh frozen plasma (FFP), and cryoprecipitate, [54] which is given in Table 2.

Table 2. American Society of Anaesthesiology guidelines for transfusion of blood products

Hemoglobin level of <6 g/dL on cardio-pulmonary bypass
Hemoglobin level of <7 g/dL in patients aged >65 years or patients with chronic cardiovascular or respiratory disease
Acute blood loss of >1500 mL or .30% of blood volume
Evidence of acute blood loss without evidence of control of bleeding

Source: Adapted from Ferraris et al. [4]

During surgery, when the patient is on CPB, hemodilution is better tolerated and various studies found that hematocrit levels of <17–19% were associated with increased mortality. [51, 55] Karkouti et al. [56] found that each percent decrease in hematocrit during CPB was associated with a 10% increase in the odds of perioperative stroke after controlling of other confounding variable. Another study found that a hematocrit level of 22% was associated with increased risk of stroke, myocardial infarction, low cardiac output, cardiac arrest, renal failure, prolonged ventilation, pulmonary edema, reoperations due to bleeding, sepsis and multi-organ failure and consequent increased mortality, hospital stay, and cost. [57] But unfortunately these studies did not study the role of transfusions on the outcome. An observational study [58] concluded that although anemia due to hemodilution during CPB increased the risk of low cardiac output after surgery, transfusion of 1–2 units of packed red cells caused an additional 27% risk adjusted risk regardless of lowest hematocrit. Another study of about 2000 patients undergoing first time isolated CABG showed that only 34% of the patients received a transfusion in the hospital stay. [59] These patients were more likely to be older, smaller, female, and more likely to have other co-morbidities. The transfused patients had twice (15% vs. 7%) 5-year mortality. Another study found a correlation with postoperative infection and use of transfusion. [60]

One randomized controlled trial [59] conducted in patients undergoing cardiac surgery to assess transfusion strategies (<30% hematocrit; <10 g/dL hemoglobin vs. <24% hematocrit; <8 g/dL hemoglobin) concluded that there was no difference in combined mortality and morbidity outcome rate, mortality was increased in the low threshold group (hazard ratio 1.28) although it was not statistically significant. Another study [61] done on high-risk patients undergoing cardiac surgery with restrictive and liberal strategies for blood transfusion, based on hemoglobin levels during and after CPB of <7.5 and 8.5 g/dL vs. <9.5 and 10 g/dL, respectively, showed similar results. Another multicenter, international, randomized controlled study (TRICCS III) is enrolling patients to study the same in a larger number of patients and may be able to provide some guidelines in this regard.

The indications of other products are often more complicated due to difficulty in assessing the cause of bleeding and requirement of specific product. In recent years, these decisions have been made easy by use of point of care (POC) devices, which is discussed later in the chapter.

BEST PRACTICES FOR REDUCING TRANSFUSIONS IN CARDIAC SURGERY

Risk Assessment and Use of MSBOS

The first and foremost step for reducing the transfusion requirements in cardiac surgery is to identify the patients at high risk and devise various strategies to modify the risk factors if possible or to take adequate measures during various phases before during and after surgery to reduce the risk of bleeding and consequent transfusion requirements. The major risk factors have been discussed above.

In addition, this also allows the surgeons and blood banks to devise mechanisms to reduce the wastage of blood/products after cross matching. One such strategy is to use the MSBOS, which is a table of elective surgical procedures and lists the number of units of blood to be cross matched before surgery. The concept was first given by Friedman in 1976 to reduce the wastage of blood and blood products. [62] The lists need to be developed at individual centers for the procedures that are performed there and from their experience of usage of blood products. This acts only as a guide and requirement is modified according to the individual case if needed. The basis of MSBOS is to cross-match twice the median requirement for that procedure.

Preoperative Interventions

Of the above listed risk factors (Table 1), only two (anti-platelet therapy and anemia) are subject to modification in the preoperative period and are discussed in the below sections.

Antiplatelet Therapy

Antiplatelet drugs are used more and more commonly in patients undergoing cardiac surgery, especially CABG for prevention of stent/graft thrombo-occlusion. Continuation of

these drugs before surgery is associated with increased risk of bleeding and therefore transfusion of allogenic blood products. Therefore, one must manage the antiplatelet drugs before surgery to minimize bleeding while also not exposing the patient to unnecessary risk of acute coronary event. Patients with thrombocytopenia or with thrombasthenia are more sensitive to antiplatelet therapy and require various strategies to reduce bleeding and transfusion risks including preoperative stoppage of these drugs.

Low-intensity antiplatelet drugs like aspirin may be continued in patients with acute coronary syndromes but should be stopped 2–3 days before surgery in patients undergoing elective surgery. [4] Dipyridamole was shown to be associated with reduced risk of postoperative bleeding by preserving platelets during surgery initially, but later studies could not confirm this. Currently, there is no evidence to use this drug alone or in combination with aspirin in coronary artery disease patients.

Thienopyridines drugs, which inhibit platelet P2Y₁₂ receptor (clopidogrel, prasugrel, and ticagrelor) and reduce adenosine diphosphate (ADP)-mediated activation of platelets, are commonly used in patients with coronary artery disease and peripheral vascular disease, especially in patients with acute coronary syndrome and after placement of drug-eluting stents either alone or more commonly as dual antiplatelet agents in addition to aspirin and are a cause of excessive bleeding in surgical procedures, both with and without use of CPB. [30, 63] Use of dual antiplatelet therapy (aspirin plus clopidogrel) before angiography in patients who later required CABG has been found to be associated with lower incidence of ischemic events without significantly increased bleeding as compared with withholding clopidogrel until after angiography, [64] but this was achieved by withholding clopidogrel for 5 days before surgery wherever it was possible. It is recommended that these drugs are stopped at least 3 days before surgery if possible. [30, 63] This recommendation is based on assumption that with ~30% clopidogrel resistance, addition of clopidogrel to aspirin exposes 70% of CABG patients to the risk of additional bleeding while reducing only 2–3% ischemic events. [30] Similarly, there is inadequate current evidence to support addition of another antiplatelet agent to aspirin after CABG for reducing graft occlusion and adverse ischemic events, but it unnecessarily exposes these patients to increased risk of bleeding if a reoperation is required. Dual antiplatelet therapy is only recommended currently in patients with drug-eluting stents or those presenting with acute coronary syndrome at the time of CABG. [30]

Another tricky situation is a patient who has a patent drug-eluting coronary stent and is on dual antiplatelet therapy and requires cardiac surgery. Stoppage of antiplatelet therapy may result in acute stent thrombosis and may not be advisable. In this situation, if the surgery is emergent, the drugs are continued and other precautions are taken to reduce perioperative bleeding including transfusion of platelets if required, with or without help of platelet count and function testing to guide platelet therapy. In an elective situation, the patient may be shifted to other short-acting antiplatelet agents like glycoprotein IIb/IIIa receptor inhibitors (tirofiban, eptifibatide) before surgery. [4] Another drug in this class, abciximab is a long-acting drug and should not be used for this purpose. If the patient requires urgent surgery following coronary stenting with drug-eluting stenting where the patient has received large doses of various antiplatelet agents including glycoprotein inhibitors, a cautious approach is required during surgery to limit bleeding and to judiciously use blood products including platelets. As there is variability in responsiveness to antiplatelet therapy due to compliance as well as pharmacogenetic factors, POC testing for platelet ADP responsiveness may be used to determine the continuation or discontinuation of antiplatelet agents before surgery.

Other Antithrombotic and Antiplatelet Drugs

Heparin is almost an universally used drug in patients with acute coronary syndrome and has been found to be safe in patients receiving thrombolysis. [4] As most patients undergoing cardiac surgery with or without CPB receive unfractionated heparin intraoperatively, and the fact that heparin action can be reversed with protamine, unfractionated heparin may not be associated with increased risk of bleeding and transfusions. Although concerns regarding heparin rebound, heparin resistance, and heparin-induced thrombocytopenia or platelet dysfunction remain. Low molecular weight heparins, on the other hand, have been associated with increased risk of perioperative bleeding and transfusion of blood products especially if the dose was given within 12 h before surgery. [65]

Direct acting thrombin inhibitors such ashirudin, bivalrudin, and argatroban are recently developed drugs to be used as antithrombotic agents in patients with cardiovascular disease. The advantage of these drugs that there is a predictable response is countered by the disadvantage of inability to monitor the effect and non-availability of any drug to reverse their effect. They find their use mainly in patients with heparin-induced thrombocytopenia. At this point, experience with these drugs in patients undergoing cardiac surgery is limited. [4] Oral anticoagulants should always be stopped in patients undergoing cardiac surgery, and patient should be switched over to intravenous heparin. The patient should be operated once the international normalized ratio (INR) becomes less than 1.5. If this is not possible, the effect may be minimized by using vitamin K along with FFP.

Erythropoietin

EPO is a glycoprotein hormone that stimulates red cell production and is usually excreted from kidneys in response to anemia and tissue hypoxia. Its production is severely reduced in patients with chronic renal failure. Now it is commercially available as recombinant human EPO as is primarily used in chronic renal failure patients to treat anemia. A meta-analysis of many studies found that its use in the preoperative period, especially following autologous donation in both adults as well as children undergoing cardiac surgery, helped in reducing preoperative anemia and also helped in reducing transfusion requirements in the perioperative period. [66] Its main side effect is hypertension, and adequate iron supplementation is required along with EPO to get the proper red cell production and desired hemoglobin levels. [30] But at this point of time, there is little evidence regarding cost-effectiveness of this strategy in routine patients and it is only recommended in special situations such as Jehovah's witnesses, chronic renal failure, and anemia as an "off-label" application. It needs to be given at least 1 week before surgery as its effect takes 4–6 days.

Preoperative Autologous Donation

Although not routinely used due to various concerns in patients with cardiac disorders, preoperative autologous donation of up to 2 units of blood, few days to few weeks before surgery has been found to be safe and effective in reducing need of allogenic transfusions. It may be coupled with EPO and iron therapy for best results. [4, 67]

Intra-Operative Interventions

Intraoperative Autologous Donation

In this technique, 1–2 units of blood are removed from patient immediately before commencement of CPB which is replaced with crystalloid or colloid in 1:1 ratio. During CPB use, hematocrit values are used to guide transfusion (collected autologous blood followed by allogenic red cells if needed). The results of this technique have been equivocal with some studies showing benefits, while others failed to show any benefit. Also, there is a risk of hemodynamic compromise in sick high-risk patients like unstable angina, cardiogenic shock, etc. At present, it may be used in some selective patients as part of the multimodality approach. [4]

Pharmacological Agents

Antifibrinolytic Drugs

These drugs include Epsilon-aminocaproic acid (EACA), tranexamic acid, and aprotinin. The first two drugs are classified as lysine analogues [4] and act by inhibition of fibrinolysis through inhibition of plasminogen inhibitors and antiplasmin activity. These drugs bind to the lysine binding sites of the plasminogen molecule. Tranexamic acid is about 10 times more potent as compared with EACA. Aprotinin, a bovine protein, is a serine protease inhibitor, especially plasmin and acts by reducing fibrinolysis, inflammation, and thrombus generation. Aprotinin (low dose; 1 million KIU or high dose; 6 million KIU) and lysine analogs reduce the need for blood transfusion, total blood loss, and re-exploration for bleeding (high-dose aprotinin only). Although these drugs have been in use in cardiac surgery to reduce bleeding during and after cardiac surgery, especially the ones done using CPB for many years, there have been concerns regarding their safety and efficacy, especially after publication of blood conservation using antifibrinolytics trial (BART), [68] which showed that there was a significantly increased risk of 30 day mortality in the aprotinin group as compared with lysine analogs. There have been more randomized trials and meta-analyses after this study, showing risk as well as benefits of aprotinin and resulting in newer guidelines for their use. The current recommendations [30] suggest that as aprotinin significantly increases mortality, stroke, renal failure, and heart failure, its routine use in low- to moderate-risk cardiac surgeries is not recommended. However, it may be beneficial in infants and in patients at greatest risk of perioperative bleeding and is special group patients like Jehovah's Witness. Lysine analogs are indicated to reduce risk of bleeding in moderate-to high-risk patients as their efficacy is lesser as compared with aprotinin and their side effects are less well studied. An ongoing trial (aspirin and tranexamic acid for coronary artery surgery trial) is currently enrolling patients and will be able to provide more information.

Another use of antifibrinolytic drugs is to use them topically into the surgical field after cardiac surgery with CPB. Use of CPB is associated with activation of tissue factor, which combines with factor VII and forms a complex that activates other coagulation factors and then generates thrombin, which converts fibrinogen into fibrin. The normal control over this activity by antithrombin is not enough in cardiac surgery with CPB. This along with fibrinolysis caused by thrombin induced tissue type plasminogen activator results in

consumptive coagulopathy. Antifibrinolytic agents reduce bleeding after cardiac surgery and CPB by limiting this process. Aprotinin (1 million KIU in 100 mL saline) as well as tranexamic acid (1 g in 100 mL saline) is poured in the surgical field just before closure of sternum and clamping of chest drains during wound closure. A meta-analysis of 7 trials involving 525 first time cardiac surgical procedures with CPB found that use of topical antifibrinolytic agents was associated with significant reduction in 24 h chest drainage after surgery. [69]

Desmopressin Acetate

1-Deamino-8-D-arginine vasopressin (DDAVP) or desmopressin acetate acts to limit bleeding by releasing endogenous factor VII precursors, von Willebrand's factor and tissue-type plasminogen activator by acting on vascular endothelial cells and has been tried in cardiac surgery in an attempt to reduce post-operative bleeding transfusion requirements. At present, its use is not recommended routinely. It can be used preoperatively in patients with inherited or acquired platelet dysfunction, identified by using POC device PFA 100 to reverse platelet dysfunction to reduce bleeding and need for transfusion of blood and blood products. [70]

Salvage of Red Cells

Use of a cell saver system (collection of blood from the surgical site by suction, centrifugation of collected blood, and reinfusion of red cells collected after centrifugation) to salvage the red cells from shed blood in mediastinum is a useful technique in blood conservation strategy, especially in those operations where CPB is not used (off pump surgery, closed heart surgery, aortic surgery, etc.) and the blood cannot be returned to the CPB circuit. Initially, the technique was used for surgical procedures on CPB. The safety is well established with no adverse events such as central nervous system events, infections, hemolysis, air, or fat embolism along with lesser markers of inflammation. [4] There is a risk of loss of coagulation factors with resultant bleeding diathesis in patients with massive bleeding and use of cell saver to salvage the red cells. It is contraindicated in patients with infections and if the blood has been exposed to topical haemostatic agents. The current literature suggests that it is not cost-effective for routine cardiac surgery but may be useful adjunct to other methods in high-risk patients. [30]

Platelet Plasmapheresis

Use of platelet plasmapheresis results in selective removal of concentrated platelets (platelet rich plasma) from the patient, which then can be transfused to the patient after completion of the surgical procedure and CPB. This is based on the fact that CPB is associated with platelet destruction as well as dysfunction, and this strategy spares platelets from the effect of CPB. Many studies, done till date, [30] have shown variable results. In addition, there are cost and difficulties involved in the procedure and possibility of hemodynamic instability during the procedure and risk of contamination of harvested product. At present, it is only recommended in only high-risk patients if there is a reasonable chance of getting adequate platelet yield.

Concentrates of Factor IX, or Clotting Factor Complexes

Factor IX activation by tissue factor-activated factor VII complex is an important step in clot formation. Therefore, concentrates of factor IX or clotting factors in which factor IX was also present have been used in cardiac surgical procedures to reduce bleeding in patients with hemophilia B or as prophylaxis in some Jehovah's Witness patients who are ready to accept processed blood products such as these concentrates, as a part of prothrombin complex concentrate (Beriplex) for reversal of effect of Coumadin analogs like warfarin before surgery and in patients with factor VII inhibitors to bypass factor VII inhibitor activity. [30] They are not recommended for routine use.

Use of Minimally Invasive Procedures

It is known that use of CPB and aortic surgery are associated with increased risk of bleeding and need for transfusion. Therefore, it is assumed that use of minimally invasive techniques and prevention of CPB use may be associated with reduced transfusion needs in cardiac surgical practice.

Off Pump Surgery

There has been increasing use of off pump surgery especially for coronary artery bypass surgery with standard sternotomy or using minimally invasive approaches with or without use of endoscopic tools or robot. One of the suggested benefits of off pump surgery was reduced risk of bleeding and transfusion requirements. [4, 30] A large, multi-centric, randomized trial [71] of off pump vs. on pump coronary artery surgery in high-risk patients (CORONARY trial) found that there was significant reduction in the rate of transfusion on off pump group (50.7% vs. 63.3%) despite significantly lesser use of anti-fibrinolytic agents (26.1% vs. 37.0%). There was also a significant lesser need for re-exploration for bleeding with off pump surgery (1.4% vs. 2.4%).

Endovascular Repair for Aortic Diseases

In recent years, more and more patients with thoracic aortic pathology, especially descending thoracic aortic aneurysm, are undergoing repair by placing endovascular stent grafts (thoracic endovascular aortic repair or TEVAR). A meta-analysis suggests that TEVAR is associated with reduced number of patients requiring transfusions (3.9% vs. 83.7%) and reoperation for bleeding (0.01% vs. 6.5%) along with other clinical outcomes including death and renal dysfunction as compared with open aortic surgery. [72]

Type of Oxygenator and Blood Pump for CPB

Although there were many types of oxygenators used for CPB in the past, at present almost all centers use membrane oxygenators. Among other benefits, they are also associated with reduced need for blood transfusion. [4] There is no difference in terms of transfusion requirements in membrane oxygenators with closed or open venous systems.

The blood pump used for aortic return of oxygenated blood from CPB may be roller or centrifugal. Although there are theoretical advantages with centrifugal pumps (reduced complement activation and preservation of platelet function), there is no proven clinical benefit of use of centrifugal pump over roller pump in terms of bleeding or transfusion needs. [4] Another aspect of CPB is use of suction to retrieve the blood from operative field to oxygenator and to get a better view in the surgical field. If there is prolonged or high suction pressure use, there is increased risk of damage to blood components including red cells and platelets. This increases the need for transfusion and risk of bleeding. It is advisable to use the CPB suckers for keeping the operative field clean judiciously.

Biocompatible CPB Circuits, Microcircuits, and Vacuum-Assisted Venous Drainage

There is need for tubing and connectors to establish CPB for cardiac surgery. These tubing are made of medical grade PVC. When the blood comes in contact with these tubing and oxygenators, there is damage to the components of blood and activation of platelets, and coagulation and inflammatory proteins. Apart on other adverse clinical effects, these effects of contact of blood to artificial surface also lead to increased risk of bleeding and resultant transfusion requirements. Various types of heparin and heparin polymer bonded CPB circuits are available in market for clinical use. There is some evidence that use of these circuits; especially third-generation heparin polymer coated circuits may be associated with reduced blood loss, transfusion requirements, and re-exploration for bleeding. [73] Their use may be justified in high-risk patients.

Microcircuits using either minimized circuits or integrated centrifugal pump with oxygenator circuits reduce priming volume and resultant hemodilution and also reduce the surface area in contact with blood. They are particularly useful in patients with reduced body surface, preoperative anemia, and in children due to reduced hemodilution. The current evidence suggests that these circuits result in reduced bleeding and postoperative transfusion [74] along with reduction in release of inflammatory markers. The only problem with these circuits is that there is either no venous reservoir or a closed one. Closed reservoir may lead to air in the system and air lock while no reservoir carries risk of exsanguination if there is uncontrolled bleeding during CPB and surgery. A vacuum-assisted venous drainage (VAVD) has been proposed either alone or along with microcircuits in place of standard gravity-assisted drainage has been shown to help with reduced bleeding and chest drainage and thus reduced blood transfusion. [30] Again there is a risk of increased air microemboli and hemolysis with use of VAVD, and therefore this is not routinely used in cardiac surgery practice. However, it may be used with care in high-risk patients along with other measures.

Reduction of Loss of Blood in CPB Circuit

In standard CPB for cardiac surgery, priming is done with crystalloid and some of the extra volume of crystalloid is added during cardioplegia and suction of topically used saline.

This results in residual volume after completion of bypass and if this volume is discarded, there is risk of need for blood transfusion to correct anemia in the postoperative period. Various techniques may be used in isolation or in combination to reduce this loss of red cells. Retrograde autologous priming of the CPB circuit is a method to replace the crystalloid prime of the circuit with patient's blood just before starting bypass. It is first done through arterial route after placement of aortic cannula and then through venous system after placement of venous drainage cannula. Due to increased risk of air embolization, VAVD should not be used with this technique. This technique results in reduced need for blood transfusions. [4]

Hemofiltration or ultrafiltration devices may be used in parallel to the CPB circuits to filter out water and other low molecular weight substances from blood in circuit to reduce hemodilution. In the conventional technique, ultrafiltration is used during CPB while in modified ultrafiltration; it is done after completion of CPB. Although both techniques have been shown to reduce need for transfusion, modified ultrafiltration seems to be superior to conventional ultrafiltration. [30, 75] Another technique, called zero balance ultrafiltration, employs ultrafiltration with replacement of filtered volume with equal volume of balanced electrolyte solution during bypass may help reduce effects of inflammation but does not help with transfusion requirements. Microplegia is a technique in which instead of crystalloid cardioplegia or 4:1 blood–cardioplegia to arrest the heart for the cardiac surgical procedure, a mixed blood (from CPB circuit) with concentrated cardioplegia solution is used with use of a special pump in the CPB machine. At present, its effect on use of blood products is not known. Salvage of pump blood, either directly without any processing or after processing it by centrifugation or ultrafiltration, is often used in practice of cardiac surgery to limit loss of blood and to reduce need for transfusion. Although many studies have been done in recent years, mostly with small number of patients undergoing on pump coronary artery surgery, most fail to show any significant benefit in terms of reduction of transfusion, postoperative hemoglobin levels, or postoperative chest drainage. [30]

Topical Hemostatic Agents

Although there is no substitute for proper surgical hemostasis, in surgical practice, especially cardiovascular surgery, there is a need for topical haemostatic agents. These agents are useful to seal the anastomotic sites to reduce bleeding. These agents work either by compression or by sealing of anastomotic site by clot or synthetic agents. Table 3 lists various agents used for this purpose, their mechanism of action and disadvantages if any. At present, there is little evidence about efficacy or superiority of any one agent or one agent over another, limiting evidence-based use of these products. Based on individual reports, series, and some randomized studies, it may be advised that these agents can be used in high-risk patients to reduce risk of bleeding from anastomotic sites after adequate surgical hemostasis is achieved. [30]

Postoperative Interventions

Although management of bleeding and related blood conservation is similar in the perioperative period, management in the postoperative period involves reducing bleeding and utilization of shed mediastinal blood.

Use of Positive End Expiratory Pressure Ventilation

Increased Positive End Expiratory Pressure Ventilation (PEEP) when the patient is on mechanical ventilation after cardiac surgery may be effective in reducing excessive postoperative bleeding by mechanical compression of myocardium. The pressure of PEEP used ranges from 5 to 25 cm water. Available evidence suggests that it is not useful as prophylactic measure but may be effective in few patients with excessive bleeding in the postoperative period. [4] The disadvantage of excessive PEEP is effect on hemodynamics caused by cardiac compression, resulting in tamponade-like situation.

Reinfusion of Postoperative Shed Mediastinal Blood

There are many reports suggesting benefit of reinfusion of postoperative mediastinal shed blood to decrease blood transfusion. It is not recommended to re-infuse this blood directly because of the risk of infection, inflammation, and activation of extrinsic pathway of coagulation. However, it can be re-infused after treating it through a cell saver. This is useful especially in high-risk patients along with other interventions to limit transfusions. [4]

Table 3. Topical hemostatic agents

Hemostatic agent and its composition	Mechanism of action	Disadvantage
Bio-absorbable gauge of oxidized cellulose in form of woven sheets of fibers	Compression, promotion of clotting by activation of platelets, also have bacteriostatic properties	Depend on normal clotting system, less effective in the presence of coagulopathy
Microfibrillar bovine collagen	Platelet activation to promote clot formation and wound sealing	May cause organ damage if returned to circulation
Bovine fibrillar collagen/gelatin with thrombin (bovine or recombinant human) and autologous plasma	Platelet activation and clot formation with compression	Risk of antibody formation
Fibrin glue (fibrinogen plus thrombin and aprotinin)	Fibrin matrix to seal the wound	Rare risk of anaphylactic reaction
Synthetic cyanoacrylate polymers (biodegradable)	Synthetic sealant without any need of clotting system	
Synthetic polymers of polyethylene glycol	Formation of matrix sealant by action of polymers with proteins	Limited efficacy in active bleeding, use limited to seal anastomosis before resumption of blood flow
Mixture of bovine albumin and glutaraldehyde	Clot sealant formation without need of intrinsic pathway by denaturated albumin	Risk of glutaraldehyde toxicity
Large surface area polysaccharide hemispheres (plant-based polysaccharide with large surface area)	Dehydration on the surface of contact to concentrate blood cells and proteins	
Chitin-based sealants (natural polysaccharide polymer)	Formation of clot by direct action on red cell membrane may induce local growth factors	

PROCEDURES AND PRACTICES IN POSTOPERATIVE ICU

As there are many practices in ICU requiring testing of blood for various investigations including blood gas analysis, it may be a significant source of blood loss, especially in patients with prolonged ICU stay. Therefore, methods have been devised to limit this part of blood loss by using small-volume tubes, not discarding blood in the arterial line and limiting use and frequency of laboratory investigations along with use of oxymetry in place of blood gas analysis. These measures have been shown to reduce need for transfusion without compromising on safety in a cost-effective manner. [4, 76]

Special Situations

There are some special situations which warrant specific management protocols during various stages of the cardiac surgical procedure (pre-, intra- and postoperative periods) and need to be discussed separately.

Role of Hypothermia

Hypothermia has been used in cardiac surgery as an adjunct to CPB since the inception of cardiac surgery. It may be used with or without total circulatory arrest. Hypothermia helps in protecting organs, most importantly brain, liver, and kidneys, during periods of circulatory arrest of reduced blood flow that is often required to perform exact surgical procedures in patients with complex cardiac defects like congenital heart disease and disease of ascending aorta, arch, or descending thoracic aorta. Hypothermia acts by decreasing metabolic rate and oxygen consumption, preserving high energy phosphates and reducing excitotoxic neurotransmitters. [77, 78] But these advantages come at the cost of increased postoperative bleeding and increased incidence of blood and blood products transfusion apart from the increased rate of wound infections and delayed recovery from the effect of anesthetic drugs. [79] Coagulopathy induced by hypothermia results from platelet dysfunction (due to reduced release of thromboxane A₂) and inhibition of enzymatic reactions of coagulation pathway. Therefore, avoiding hypothermia if possible and maintaining normothermia in postoperative period help in reducing bleeding and transfusions. If hypothermia is inevitable, one must use plasma and platelets to restore clotting mechanism and reduce need for red cell transfusion. [77, 80]

Cold Agglutinins

Cold agglutinins are mostly IgM antibodies that react with surface antigens of red blood cells at cold temperatures, leading to hemagglutination followed by complement fixation and hemolysis on warming. They also result in myocardial dysfunction by blocking coronary microcirculation if cold blood cardioplegia is used for myocardial preservation during aortic cross clamp. [81] They may also result in intravascular thrombosis, embolization and tissue

ischemia or infarction of various organs. These antibodies may be primary (idiopathic) or secondary due to infections such as mycoplasma, infectious mononucleosis or other viral infections, or due to lymphoproliferative disorders. They rarely are clinically apparent due to activity at low temperature. It is recommended that routine cross matching for cardiac surgery should also include testing and estimation of titer of these antibodies along with their thermal amplitude (temperature below which antibody get activated). The incidence of cold agglutinins in cardiac surgery is 0.8–4%. [82] Although most patients are asymptomatic, some patients with high titers and or high thermal amplitude can show signs of hemagglutination (peripheral ischemia, hemolysis, etc.) at low temperatures. If the diagnosis is not made before, it can be suspected by the presence of visible agglutination in cardioplegia circuit, intracoronary thrombosis, and inadequate cardioplegia delivery with high line pressures in the CPB circuit.

The management plan includes preoperative detection. If the antibodies are present, one must test for the presence of autoimmune hemolytic anemia (AIHA). If AIHA is present, one must involve a hematologist and a transfusion medicine specialist in the management of these patients. If AIHA is absent, the management involves avoidance of CPB (off-pump surgery), hypothermia (normothermic CPB), and cold cardioplegia (use of warm cardioplegia). Sometimes preoperative plasmapheresis or immunoglobulin G therapy may be required if hypothermia cannot be avoided for the surgical procedure. [81, 83] If intraoperative agglutination is detected, the patient should be re-warmed to normothermia and the coronaries should be flushed using warm crystalloid cardioplegia. Other measures are aimed at management of hemolysis and other organ damage if present.

SPECIAL ISSUES IN CHILDREN, ESPECIALLY WITH CYANOTIC CONGENITAL HEART DISEASE

Children cannot be treated like small adults and therefore, strategies used in adults should not be scaled down and used in children who undergo cardiac surgery. The most important factors to consider in children are their small circulating volume and tendency to develop hemodynamic instability with small changes. Therefore, important considerations are limiting priming volume and using drugs like tranexamic acid or aprotinin to decrease risk of bleeding and transfusion requirements. Role of best practices in ICU may not be overemphasized in children.

Other important consideration in children is the presence of cyanotic congenital heart disease, which is one of the most important causes of cardiac surgical procedures in children. These children have associated deficiencies of coagulation factors and thrombocytopenia. [77] Use of minicircuits, priming the pump circuit with colloid instead of crystalloid, avoidance of hypothermia, etc. are most important tolls to decrease the risk of bleeding in these children. One should use FFP and platelets as required, depending of laboratory values and hemodynamic status of the patient to decrease bleeding and limit use of red cells. [84]

VADS, EXTRA-CORPOREAL MEMBRANE OXYGENATION, AND HEART/HEART–LUNG TRANSPLANTATION

These are the sickest patients in practice of cardiac surgery, requiring long-term circulatory/pulmonary support. Use of these circulatory support devices, in isolation for management of patients or in conjunction with heart transplantation (preoperatively till the heart is available or postoperatively if the organ is rejected), is associated with increased bleeding disorders and need careful management of blood resources. [85] Use of VAD and ECMO is associated with bleeding from cannulation site, surgical incision and gastrointestinal or intracranial bleeding along with risk of clotting in circuit and thromboembolic complications. [30, 86] There are guidelines for VAD and ECMO management which include heparin use (activated clotting time between 180 and 240 s), use of heparin bonded circuits, use of non-heparin anticoagulants if HIT is present and use of antifibrinolytic agents. The role of POC testing to direct use of various blood products cannot be overemphasized in these patients. [77, 87] Anticoagulation management of long-term VAD support is beyond the scope of this chapter.

Role of Electrocautery and Harmonic Scalpel in Transfusion Management in Cardiovascular Surgery

Although the best method of dissection in surgical practice is sharp dissection using knife and scissors, it leads to bleeding and damage to cardiac structures. Electrocautery of bleeding vessels and for dissection may reduce bleeding, but it may also result in inadvertent damage to cardiac structures. A safer method of electrocautery is to use bi-polar cautery for bleeding vessels. A new method for dissection, cutting, and control of bleeding is harmonic scalpel, which works with ultrasonic energy. [88] It has been shown to be useful in decreasing bleeding as well as transfusion requirements in cardiac surgery, especially in patients undergoing re-do cardiac surgery or those undergoing pericardiectomy for constrictive pericarditis. [89]

Role of Perioperative Blood Testing

There is a role of use of conventional clotting tests (CCT) like bleeding time, clotting time, prothrombin, and activated partial thromboplastin time (PT and APTT), fibrinogen level, testing for D-dimer along with measurement of hemoglobin, hematocrit, and platelet count in patients undergoing cardiovascular surgery to determine high-risk patients for bleeding, correction of abnormalities in the preoperative period if feasible and taking adequate measures in the operating room and ICU to decrease risk of bleeding and need for transfusion of blood and blood products. The CCTs have limitations like measurement of only individual coagulation component/mechanism; no measurement of interplay between various parts of coagulation pathways and little correlation with clinically significant coagulopathy or bleeding. Furthermore, most of these cannot be used as POC tests resulting in delay in decision making. [4] POCs are the tests, which are available at the bedside (in

operation room or ICU) and have a turnaround time of 10–20 min. Most common tests are based on viscoelastic hemostatic assay and include thromboelastography (TEG; Hemoscope Corporation, Niles, IL, USA) and rotational thromboelastometry (ROTEM; Tem International, GmbH, Munich, Germany). Both these tests provide a graphic analysis of clot formation and subsequent lysis.

Various parts of the graph give information on initiation speed of clotting, thrombin generation and fibrinogen cleavage kinetics, clot strength, and clot lysis and indicate the component/s of the clotting mechanism that are dysfunctional thus providing goal-directed transfusion of prevention as well as therapy of bleeding. [90] A recent study showed that POC testing was superior to CCT in prediction of bleeding, need of re-exploration, and reduction of need for blood transfusion. [91] Other POC devices which are useful are platelet function analyzer 100 (PFA-100; Siemens Healthcare Diagnostics, GmbH, Eschborn, Germany) and whole blood impedance aggregometry (Multiplate) for platelet function analysis and FIBTEM (Tem International GmbH, Munich, Germany) for analyzing fibrin polymerization. There are also devices to measure isolated function of clotting pathway (EXTEM for extrinsic pathway, INTEM for intrinsic pathway, HEPTEM for heparin effect, ACATEM for direct thrombin inhibition, and APTEM for fibrinolysis; all from Tem International, GmbH, Munich, Germany). Although these POC devices are useful adjunct to management of transfusion and bleeding in patients with cardiovascular surgery, [87, 92, 93] they are expensive, not routinely available and the cost of each test is also high. Figures 1–3 show flow charts for transfusion practices in cardiovascular surgery. These should be used as suggestive only and exact patient management should be done by a multispeciality team and locally derived guidelines keeping in mind both the cost as well safety to the patient.

Figure 1. Pre-operative risk assessment as a strategy for best practices.

Management of Heparin and Protamine during Surgery, Heparin Resistance, and Heparin-Induced Thrombocytopenia

The most commonly used anticoagulation agent during cardiac surgery and for CPB is heparin, which is reversed after surgery with protamine. Heparin and protamine management during cardiac surgery needs to be understood to decrease bleeding problems and serious catastrophe. Heparin acts by binding with serine protease antithrombin III (AT), which in turn binds with thrombin and other coagulation factors including factor Xa and inhibits them. Heparin also reduces consumption of coagulation proteins and platelets and is also helpful in decreasing transfusion requirements. It also prevents clotting in the CPB circuit. [4, 30] It also helps by inhibiting many other sites in intrinsic and extrinsic pathways. Traditionally heparin dosing is either fixed or guided by activated clotting time (ACT) measurement, which has not been shown to consistently decrease bleeding and transfusion requirements in cardiovascular surgery. [4, 30] In comparison, use of a POC system (Hepcon; Medtronic Blood Management, Englewood, CO, USA) not only reduced total heparin and protamine dose, but also resulted in [94] reduced requirement of platelets, FFP and cryoprecipitate along with reduced postoperative bleeding.

Figure 2. Best practices in management of bleeding in cardiovascular surgery.

Impaired heparin response or heparin resistance (HR) is most commonly due to AT deficiency but may also occur due to heparin binding to various cells and proteins. Other factors responsible for HR are its origin (intestinal vs. lung; bovine vs. porcine), method of preparation, and molecular weight distribution of various heparins in the prepared heparin. HR is defined as failure to achieve target ACT (400–480 s) after standard dose of heparin (400–1200 U/kg body weight). HR has been traditionally treated by FFP or AT concentrate (plasma derived or recombinant). [95] As compared with FFP, AT concentrates are advantageous in not only restoring heparin responsiveness but also in suppression of thrombin generation and fibrinolysis associated with use of CPB. [96] This results in less bleeding, blood transfusion as well as lesser incidence of thromboembolic complications. [30,

97] Protamine is the agent used to neutralize the effect of heparin after completion of CPB. It is usually used empirically (50% of total heparin dose used). As protamine itself is an anticoagulant, its over or under dose is associated with increased risk of bleeding. Recent evidence suggests that use of POC systems to titrate dose of protamine (for example, by RxDx system; International Technidyne, Edison, NJ, USA) results in use of lower dose of protamine, reduced postoperative bleeding, and need for blood transfusion. [98]

(A 10, amplitude of clot firmness 10 minutes after clotting time; CT, clotting time; EX, EXTEM; Tem international, Munich, Germany; ROTEM test activated by tissue factor; FIB, FIBTEM; Tem international, Munich, Germany; ROTEM test activated by tissue factor and block of platelet function by cytochalatin D; HEP, HEPTM; Tem international, Munich, Germany; ROTEM test activated by ellagic acid and elimination of a potential heparin action by heparinise; IN, INTEM; Tem international, Munich, Germany; ROTEM test activated by ellagic acid)

Figure 3. Use of point of care devices (thromboelastometry; ROTEM; Tem international, Munich, Germany) for use of blood component therapy for bleeding during or after cardiovascular surgery.

Heparin-induced thrombocytopenia (HIT) is a reaction to heparin resulting in damage to platelets, thrombocytopenia, and complications like bleeding as well as thrombosis. It occurs in ~1.5–3% of all the patients exposed to heparin. It may be nonimmune-mediated (type I), which occurs early (<4 days) after intravenous heparin exposure, is dose dependent and is characterized by lower degree of thrombocytopenia and early recovery. It probably results from increased platelet aggregation and sequestration in spleen. Immune-mediated (type II) HIT occurs late (>4 days) after heparin exposure by any route, is not dose dependent, and results from formation of HIT antibodies. It is associated with >50% reduction in platelet count along with activation of coagulation cascade by activation and aggregation of platelets and thrombotic complications. The diagnosis is usually clinical and may be confirmed by platelet aggregation tests, C14 serotonin release assay, heparin-induced platelet aggregation, and various types of assays to detect HIT antibody. The treatment involves stopping any kind of heparin therapy, use of alternate anticoagulant use (bivalirudin, leupiridine, danaparoid, argotroban, etc.), and use of steroids and plasmapheresis for severe cases. [99]

CONCLUSION

Cardiovascular surgery remains to be one of the specialties requiring maximum demand on blood banks resulting in increased costs, difficulty in meeting demands due to limited supply of blood and blood products, and risks of various morbidities and increased mortality associated with blood transfusion. On the other hand, restricting use of blood and products may lead to increased bleeding and anemia with consequent effects on the outcome. Recent evidence suggests that there can be a scientific way to reduce transfusions with improved patient outcomes by team approach involving surgeon, anesthesiologist, perfusionist, transfusion medicine specialist, ICU care providers, cardiologists, nurses, and other personnel involved in care of patients undergoing cardiovascular surgery. This multidisciplinary team involving surgeons as well as non-surgeons should work together. Risk assessment, development, and use of best practice guidelines for transfusion for the institution and rational use of various methods described above for individual patients will ultimately lead to the best outcome at a reasonable cost.

ABSTRACT

Crohn's disease results in transmural inflammation involving any portion of the gastrointestinal tract from the mouth to the anus. However, Crohn's disease most commonly affects the lower gastrointestinal tract, often sparing the proximal portions. Here, we review the presentation and management of Crohn's disease of the esophagus, stomach, and duodenum. When Crohn's is referred to as a "spectrum of disease," the writer may indeed have foregut disease in mind. Like all forms of Crohn's disease, the initial management is typically medical. Unlike the remainder of the GI tract, however, bypass techniques are preferred to resection or strictureplasty techniques. Surgeons that often encounter Crohn's disease will inevitably face the patient with Crohn's of the foregut, either in isolation, or more commonly, in conjunction with ileal or colonic disease. This overview is intended to help with both the evaluation and management of foregut disease.

PREVALENCE

The prevalence of symptomatic Crohn's disease involving the esophagus, stomach, and/or duodenum has been reported to be between 0.5 and 4% [1-7]. With more liberal use of esophagogastroduodenoscopy (EGD), however, recent studies suggest that occult findings in the upper gastrointestinal tract are far more frequent, ranging from 16 to 51% [8-10]. In a retrospective review, published in 2014, endoscopic and pathologic changes of the upper GI tract in 138 patients with Crohn's disease were examined [8]. Seventy of 138 patients (51%)

* Corresponding Author's Email: skavic@smail.umaryland.edu.

demonstrated macroscopic disease-specific findings. The definition of disease-specific findings involving the upper GI tract and results of this study are detailed in Figure 1.

Location	Any findings (%)	CD specific findings* (%)	Granuloma detection (%)
Esophagus	14	7	0
Stomach: upper to mid	51	48	6
Stomach: lower	60	25	25
Duodenum: bulb	42	32	11
Duodenum: 2 nd portion	19	18	0
Total	75	51	11

* Crohn's disease (CD) specific findings included: aphthae, longitudinal/irregular erosions and ulcers, Bamboo joint appearances, protruded or notch like appearances in the duodenum and fistula or stricture irrespective of location. Esophageal lesions were considered non-CD related when relation with reflux esophagitis was suspected. Gastroduodenal lesions were considered non-CD related when relation with *H. pylori* or NSAIDs was suspected.

Figure 1. Frequency of identification of characteristic findings and granulomas on EGD, based on a review of 138 patients [8].

Presently, upper endoscopic evaluation is recommended for use only in Crohn's disease patients with upper GI symptoms. However, given that there are frequent occult findings, some argue that EGD should be included as part of the routine diagnostic work-up [9, 10]. In a prospective analysis published in 2012, 119 patients with Crohn's disease underwent histologic and endoscopic examination before and after medical therapy [10]. All symptomatic patients showed relief of symptoms following treatment, and while 63% of patients were asymptomatic at presentation, nearly half of these patients (47%) demonstrated mucosal healing on post-treatment biopsy.

The prevalence of Crohn's disease involving the foregut does not seem to vary significantly with age. In children with Crohn's disease, histologic evidence by endoscopy of the upper GI tract is also frequently documented (30-80%) [11-13]. Nonetheless, symptomatic disease in this region is uncommon.

CLINICAL MANIFESTATIONS

Isolated involvement of the esophagus, stomach or duodenum is exceptionally rare. Patients are more commonly diagnosed with disease in the terminal ileum, and symptomatic involvement of the foregut is identified secondarily. Patients with Crohn's of the foregut, often present with the signs and symptoms of Crohn's disease.

In a study by Nugent and Roy, which examined 89 patients with gastroduodenal Crohn's disease, 46 of 89 patients (52%) had documented distal disease before the development of upper GI symptoms [4]. At a follow-up interval of 12 years, distal disease had developed in 82 of 89 patients (92%); 53 of 89 patients (60%) had contiguous gastroduodenal involvement, and two of 36 patients with duodenal disease also had involvement in the proximal jejunum.

Importantly, symptoms of Crohn's disease involving the foregut can be difficult to differentiate from other more common ailments of the upper gastrointestinal tract, such as gastroesophageal reflux and peptic ulcer disease. Esophageal symptoms might include epigastric or chest pain, dysphagia or weight loss, thereby mimicking symptoms of

gastroesophageal reflux. Some patients with involvement of the esophagus may also present with oral aphthous ulceration [14].

The presenting symptoms of patients with gastroduodenal Crohn's disease from several series are outlined in Figure 2 [1, 4, 15-17]. The most common symptoms of gastroduodenal involvement included postprandial pain, nausea, vomiting, and weight loss. Notably, the pain associated with gastroduodenal Crohn's disease was relieved by antacids or acid suppressive therapy, as is seen in peptic ulcer disease.

Much like Crohn's disease that involves any region of the gastrointestinal tract, advanced manifestations of Crohn's disease in the foregut include stricture, obstruction, fistulization, or bleeding. Of these complications in esophageal Crohn's disease, stricture presents most frequently. In Decker's review, the clinical course and outcome in twenty patients with symptoms of esophageal Crohn's disease is described well. Four of twenty patients (20%) presented with esophageal stricture [14]. The overwhelming majority presented with dysphagia, and these patients were found to have esophageal ulceration and/or erosion (90%) without complication. Obstruction is the most common presenting symptom in gastroduodenal Crohn's disease, and remains the most common indication for surgery in Crohn's disease involving the foregut, ranging from 70-90% [4, 7, 19].

Symptom	Nugent and Roy [4]	Worsey [15]	Farmer [16]	Poggioli [17]
Postprandial pain	79	71	100	100
Weight loss	64	65	72	55
Nausea and vomiting	61	32	72	55
Bloating	NR	68	NR	NR
Bleeding and anemia	17	NR	9	33

NR = not recorded.

Figure 2. Presenting symptoms of gastroduodenal Crohn's disease.

Fistulization of the esophagus in Crohn's disease can also occur, involving communication with the proximal and/or distal airway, however this is much more rare [18]. Fistulas involving the stomach and/or duodenum are also infrequent, and if they arise, are more often attributed to primary colonic or distal small bowel disease. Fistulization to the pancreatic gland, although vanishingly rare, has also been described in gastroduodenal Crohn's disease [20-24]. Likewise, granulomatous involvement of the gallbladder, and common bile duct obstruction, have both been reported [23-26].

Studies examining surgical patients who present with complications of Crohn's disease involving the esophagus, stomach or duodenum, suggest that the patient population should be considered high risk. Crohn's disease of the upper gastrointestinal tract has been associated with increased recurrence, need for surgery and length of hospitalization [27, 28]. Interestingly, in a recent cross-sectional query of the National Institute of Diabetes and Digestive and Kidney Diseases Inflammatory Bowel Disease Genetics Consortium (IBDGC), published by Lazarev in 2014, 175 of 1,759 patients (10%) with Crohn's disease involving the esophagus, stomach or duodenum (EGD) were compared to patients with isolated jejunal disease, 115 of 1,759 patients (7%) [29]. In this study, while patients with EGD involvement seemed to present at an earlier age, they were less likely to have stricturing and undergo multiple surgeries. Instead, independent predictors of structuring behavior and multiple abdominal surgeries included ileal involvement, longer duration of disease and isolated

jejunal disease. Current classification schemes do not reflect a difference between Crohn's disease of the duodenum and jejunum.

DIAGNOSIS AND CLASSIFICATION

A diagnosis of subtle disease involving the esophagus, stomach or duodenum can be done endoscopically, and reported prevalence varies dramatically based on clinical presentation. This variance is further complicated by non-specific gross and/or histologic findings identified on endoscopy, as universal criteria for Crohn's disease involving the upper gastrointestinal tract have yet to be defined. While findings of macroscopic ulceration or aphthous lesions are frequently seen in Crohn's disease of the upper GI tract, erythema, edema and other inflammatory changes cannot exclusively be attributed to Crohn's disease.

The histology of gastric Crohn's disease in particular is difficult to interpret. The occurrence of epithelioid granulomas is considered a histological hallmark of the disease, however this finding is detected infrequently [1, 8, 9]. A list of commonly accepted Crohn's disease-specific findings in the upper GI tract is included in Figure 1.

Upper GI studies with contrast (typically barium) are best utilized to characterize fistulas or obstructive lesions. Although these findings are uncommon, they have been well described in the literature. The shape of the distended stomach and a rigid stenotic antrum and duodenum has been described as the "ram's horn deformity", seen in gastroduodenal Crohn's disease [30]. Similarly, a tube-like appearance of the antrum, pylorus and duodenum has been termed, the "pseudo-Billroth I", characterizing Crohn's disease which involves the stomach and duodenum as similar in appearance to a surgical end-to-end gastro-duodenostomy [31].

Current systems used to classify Crohn's disease include the Vienna and Montreal classifications. The Montreal classification system is the most recently updated version [32]. Note that this classification scheme may be revised to further subclassify L4 disease into two categories, esophageal-gastric-duodenal, and jejunal, reflecting increasing evidence that supports clinically distinct differences between the two [29].

MEDICAL TREATMENT

The current therapeutic approach to Crohn's disease accounts for the broad spectrum of disease involvement. Most clinicians, however, assume that the entire GI tract is at risk for the subsequent manifestation of Crohn's disease. As a result, patients with Crohn's disease of the foregut are treated with standard therapy, including 5-aminosalicylic acid and steroids. The efficacy of more recent immunosuppressive treatments has not been specifically evaluated in Crohn's disease of the upper GI tract, but has been reported to be successful [33, 34]. Other modalities that have been used, but have not been widely adopted, include endoscopic dilation and local steroid injection for obstructive lesions [14, 35-37].

SURGICAL MANAGEMENT

Esophageal Crohn's Disease

In general, an anastomosis to the esophagus within the chest has a significant risk of complications. This risk is amplified in patients with Crohn's disease, making resection with anastomosis particularly unappealing. Therefore Crohn's disease of the esophagus, when presenting with severe complications, requires esophagectomy.

Fortunately, esophageal disease is infrequent. Unfortunately, the consequence for surgeons is that there is a paucity of quality literature to guide management. Early case reports, from the 1960's to the 1980's, often documented very poor outcomes [38, 39]. More recent literature on the topic has focused on endoscopic and medical therapies for strictures and obstruction, as alternatives to esophagectomy [14, 35-37]. The most common endoluminal therapies include dilation, steroid injection, and topical application of other immunosuppressive regimens. Despite modern advancements in surgical technique and post-operative care, which have likely improved associated morbidity and mortality, the use of esophagectomy for surgical management of esophageal Crohn's disease should be reserved for severe cases. It is worrisome to replace the native esophagus with intestinal conduit, as a replacement with colon may lead to recurrent disease within the chest if Crohn's develops within the colon. Given the morbidity of both medical immunosuppression as well as surgical complications, it is also essential to consider first and eliminate the more common causes of chronic esophageal inflammation, such as gastroesophageal reflux.

Gastroduodenal Crohn's Disease

The most common indications for surgery in gastroduodenal Crohn's disease include obstruction and refractory painful ulceration. Isolated gastric disease is extremely rare [40, 41]. Options for surgical management of complicated gastroduodenal Crohn's disease include bypass, resection, or strictureplasty. Unlike the management of Crohn's disease involving the distal small bowel and colon, bypass is more commonly used than resection, as resection in this region is associated with significant morbidity [42]. Bypass techniques most frequently used include gastro-jejunostomy, gastro-duodenostomy, and Roux-en-Y gastro-jejunostomy.

In one of the largest and most recent studies performed on surgical management of patients with gastroduodenal Crohn's disease, Shapiro retrospectively examined 30 patients who underwent surgical intervention between 1995 and 2006 at Mount Sinai Medical Center [19]. Eleven patients underwent open bypass, thirteen had laparoscopic bypass, two underwent strictureplasty, and four had fistula takedown. The average length of follow-up was 58 months, 27% (n = 7) experienced major complications, including five patients in the open bypass group and one patient in the laparoscopic bypass group, and there was one death. The authors concluded that surgery is a viable and safe option for patients with intractable gastroduodenal Crohn's disease. Furthermore, in the era of widespread use of proton pump inhibitors, vagotomy is no longer considered necessary to prevent marginal ulceration post-operatively. Results of this study in comparison to other published series are listed in Figure 3. These studies report significant complication rates, yet serious morbidity (such as

anastomotic leak and sepsis) is uncommon, and mortality rates are also very low. A comparison between bypass and strictureplasty has not been prospectively evaluated in Crohn's disease of the upper GI tract. Initial analysis in the early 1990s, suggested that strictureplasty may be associated with a significant complication rate. In one analysis, 9 of 13 patients (69%) required reoperation for complication and/or recurrent disease. However, a more recent report from the same surgical group published a surgical recurrence rate of only 25% (2 of 8 patients) in this patient population [7, 43, 44]. Although these results represent small sample sizes, they suggest that refinements in technique can result in improved outcomes. Currently, strictureplasty remains an acceptable alternative to bypass for Crohn's disease involving the duodenum and is used according to surgeon preference.

Study (Sample Size)	Open Bypass	Laparoscopic Bypass	Strictureplasty	Vagotomy	Morbidity	Mortality
Worsey [15] (n = 34)	21	0	15	21	6 (18%)*	NR
Nugent and Roy [4] (n = 33)	32	0	0	18	8 (24%)*	NR
Yamamoto [7] (n = 23)	13	0	10	4	13 (57%)	NR
Shapiro [19] (n = 30)	11	13	2	1	14 (47%)	1 (3%)

*Morbidity in these series was recorded as recurrence requiring surgical revision.

Figure 3. Surgical management and outcomes in patients with Crohn's disease of the foregut.

Current recommendations include strictureplasty for short segment disease within a segment of small bowel when the segment is surgically accessible and the procedure may be accomplished with minimal risk to adjacent structures. Therefore, patients with stricturing disease in the second and fourth portions of the duodenum may be better served by bypass techniques (gastro-duodenal or gastro-jejunal). Disease in the first portion or third portion may be amenable to Heineke-Mikulicz strictureplasty.

Cancer Risk and Management

Small-intestinal adenocarcinoma associated with preexisting Crohn's disease has been rarely reported and requires complete oncologic resection [45-52]. Cancer of the small intestine, arising in Crohn's disease patients, has been associated with younger age at presentation and has a male predilection. There is a poor prognosis due to delay in diagnosis, often attributed to difficulty in differentiating underlying Crohn's disease and early signs of invasive carcinoma. These cases emphasize the need to perform a careful and thorough endoscopic evaluation, with the use of biopsy of any concerning lesions, to rule out malignancy in patients with Crohn's disease.

CONCLUSION

Crohn's disease isolated to the foregut is a rare condition, which more commonly manifests in association with contiguous involvement in the distal gastrointestinal tract. Crohn's disease-specific lesions are increasingly being identified with the use of upper endoscopy, and practitioners still debate when best to perform an endoscopic exam. Medical therapy continues to be the mainstay of management in the majority of patients who present with Crohn's disease involving the stomach, esophagus and/or duodenum; however surgeons still have a vital role. Surgical intervention for Crohn's disease of the foregut can be performed safely and with good outcomes, yet should be reserved for patients with severe complications and/or disease that is refractory to medical treatment.

ABSTRACT

The terminal ileum is clearly the most frequently involved portion of the intestine in patients with Crohn's disease. However, it is more difficult to discern the relative frequency of isolated small bowel involvement in this population. Strictureing disease is commonly encountered, and we review both the pathophysiology as well as the major techniques of resection and strictureplasty. An algorithm for perforating disease is also presented, as well as strategies for the management of fistulizing disease. As with other portions of the GI tract, multi-disciplinary care is the key to optimal outcomes. However, the surgeon plays a central role in the management of complicated small bowel disease, especially in cases of obstruction, perforation, and fistulization.

INTRODUCTION

It is well-known that an estimated 75-80% of Crohn's patients ultimately require surgery, with numbers as high as 50% within ten years of their diagnosis. [1] However, the precise data concerning small intestinal disease specifically are harder to discern. As the terminal ileum is the single most commonly involved segment of disease, and resection necessarily involves the cecum, there is some overlap between colectomy and small intestinal resection that increases the difficulty of interpreting the literature. In this chapter, we will examine the disease patterns that may necessitate small bowel surgery in Crohn's disease, discuss major surgical techniques of strictureplasty, and discuss preoperative and postoperative considerations.

LOCATION

Approximately 30% of patients have isolated small bowel involvement. Within the small bowel, the terminal ileum is the most common site of active disease. In fact, terminal ileal stricture causing obstruction is the classical presentation for surgically managed Crohn's disease. [2] The terminal ileal predominance of Crohn's disease extends to a variety of pathologies, including obstruction, fistula, stricture and neoplasm.

Duodenal involvement is the least common small bowel location, found in fewer than 3% of patients. Duodenal disease generally manifests with gastric outlet obstruction. Unlike terminal ileal disease, which often requires resection, the primary treatment remains immunosuppressive into the late stages of disease. [3] Once the symptoms can no longer be controlled, a bypass (gastro-jejunostomy or duodeno-jejunostomy) should be considered.

PREOPERATIVE CONSIDERATIONS

Prior to an elective operation for Crohn's disease, the first consideration is the determination of medical management of the patient. Current medical therapy provides most patients with symptomatic control, and may be preferred over surgical intervention. However, those with fibrostenotic disease may have minimal response to anti-inflammatory medications. In addition, some patients with localized disease may opt for primary surgical intervention over systemic therapies. Increasingly, the management of Crohn's disease is multi-disciplinary, and the surgeon should not hesitate to be involved early in the discussions of management options for these patients.

Once the decision to operate has been made, each patient should be optimized for surgery. Most patients will require general anesthesia, and guidelines for cardiac workup before invasive procedures have been well established. [4] Routine assessment includes basic laboratory studies (CBC, CMP, and coagulation studies), chest radiograph and EKG in most patients. It is our practice to type and screen all patients undergoing intestinal resection.

Most patients with Crohn's disease have a thorough history of localizing studies. Indeed, it is rare to find a patient requiring operation without a dossier of endoscopy, CT scans, or other contrast-based studies. It is mandatory that the surgeon review the preoperative imaging, and to repeat studies if there has been a substantial interval between imaging and operation. A CT scan is probably the most useful single test to assist in localization and the diagnosis of complex Crohn's disease. [2]

Perhaps the most important factor specific to Crohn's patients is overall nutrition status. Often, patients with Crohn's disease have poor nutrition, due to poor intake, malabsorption, systemic inflammation and medication side effects. Optimizing preoperative nutrition is critical for postoperative wound healing, particularly if a primary bowel anastomosis is constructed. It has been demonstrated in elective colorectal resections that anastomotic dehiscence is associated with hypoalbuminemia (<3.5 g/dL). [5, 6] Enteral nutritional support is preferred to optimize preoperative nutrition.

Though Crohn's disease patients may have a broad spectrum of nutritional deficiencies, components including an elemental diet and omega-3 fatty acids have been advocated by some to promote ease of digestion and prevent proinflammatory leukotriene and

prostaglandin generation, respectively. [5, 7-9] A course of total parenteral nutrition prior to surgery of at least 18-30 days is also recommended by some for nutritional repletion prior to elective surgery, though the risk/benefit ratio of this intervention has not been demonstrated. [10, 11]

The most difficult preoperative task is management of immunosuppressive therapy perioperatively. Generally, non-steroidal immunosuppressive regimens can be safely stopped just before surgery or not at all, while chronic steroid use necessitates continued perioperative use, occasionally requiring a stress dose to prevent adrenal insufficiency. [2] In the past, almost all patients received “stress doses” of corticosteroids; currently, this dogma has been challenged by the clinical experience that many patients do not require supplemental exogenous steroids. Finally, in the elective setting, a standard preoperative antibiotic regimen of intravenous cefoxitin, or ciprofloxacin and metronidazole should be administered. In the setting of an emergent operation, generally for perforating disease, a broader regimen should be considered perioperatively.

In small bowel surgery for Crohn’s disease, a bowel preparation regimen is not recommended. There is no evidence to suggest a bowel preparation mitigates postoperative complications. However, in elective colon resections for patients with any pathology, a bowel preparation has been recognized as a risk factor for anastomotic leak. [12, 13]

DISEASE PATTERNS

Obstructing Disease of the Small Bowel

The most frequent indication for surgery in Crohn’s disease patients is obstructing disease. [14] Obstructing disease in Crohn’s disease patients is thought to develop from the progressive wall thickening subsequent to recurrent bouts of inflammation. Fibrostenotic disease does not respond well to medical management as the benefits of minimizing inflammation dwindle as mural thickening stenoses the luminal diameter (Figure 1).

Figure 1. Inflammation of the intestine, in cross-section. A: Normal wall, moderate inflammation. In this setting, anti-inflammatory management will restore the luminal diameter of the intestine. B: Thickened wall, minimal inflammation. In the advanced state, medical management will have minimal effect on the lumen, and the patient will require surgical intervention for clinical relief.

Strictureing disease is quite common, and can be repaired with segmental resection or strictureplasty. In addition, an inflammatory mass such as a phlegmon or abscess, or a neoplasm, can cause bowel compression and obstruction. [15] These can be addressed medically, or via percutaneous or open surgical intervention.

The transmural inflammation of Crohn's disease also promotes fistulization between inflamed bowel and another organ, such as another segment of small bowel, large bowel, bladder or the skin, among others. Fistulizing disease often requires operative intervention when obstructive or septic complications develop. Perforating disease of inflamed small bowel can lead to peritonitis, requiring acute surgical intervention in Crohn's disease patients. Here, we will summarize the management of obstructing Crohn's disease of the small bowel.

Duodenal Obstruction

Duodenal involvement in Crohn's disease is relatively rare, occurring in 1-5% of patients. [16] The proximal duodenum is the most common location for duodenal Crohn's disease, followed by the descending portion. [17] Obstruction, generally due to structuring disease, is its most frequent presentation. The most common obstructive symptoms are abdominal pain, nausea, vomiting and early satiety. [18]

In principle, diagnosis of small bowel disease is made by upper gastrointestinal series. Early stenotic disease may show thickening and blunting of mucosal folds, cobblestoning and erosions. Progression of stenotic disease may lead to healing, scarring and fibrosis of the bowel segment.

More characteristically, deep linear ulcerations with opposing wall sacculations are seen. [19-21] More commonly, however, the diagnosis of duodenal obstruction is suggested on a CT scan, and confirmed on EGD. CT findings may include signs of gastric outlet obstruction, duodenal mural thickening, hyperemia of the mucosa, soft tissue stranding as well as sites of extra-duodenal inflammation. [20]

Although initial management is generally with antacid and anti-inflammatory medications including steroids and infliximab, [16] surgical intervention may be eventually required in up to 91% of these patients. [17] In the face of duodenal obstruction, the surgeon is faced with two options: bypass or strictureplasty. Resection of the duodenum is no longer considered a routinely viable option, as it is associated with very high morbidity and mortality; in rare cases, partial duodenectomy or even a formal pancreaticoduodenectomy may be required. [21]

Unfortunately, due to the low prevalence of duodenal Crohn's disease, the best surgical approach between duodenal bypass and duodenal strictureplasty has only been studied in small case series, and neither approach is supported with high-level evidence. Therefore, both procedures are currently considered equivalent surgical options.

Both duodenal strictureplasty and bypass often necessitate reoperation for further obstruction/re-stricturing disease, while anastomotic leak and postoperative hemorrhage have also been described as complications from both procedures. [16] For patients who receive duodenal bypass, surgical options include gastrojejunostomy, gastroduodenostomy and Roux-en-Y-gastrojejunostomy. Strictureplasty, on the other hand, allows for restoration of the constricted lumen throughout the affected portion of bowel. The operative technique is based on the length of strictured segment, and is described in detail in this chapter.

Duodenal strictureplasty is often quite difficult, however, as extensive mobilization of the duodenum is required, made difficult by extensive inflammation. The complexity is further increased due to the retroperitoneal location and proximity to sensitive vascular and pancreaticobiliary structures. [21]

Jejunioileal Obstruction

Up to 3-10% of Crohn's disease patients are affected by diffuse jejunoileal disease, with obstruction the most common indication for surgical intervention. Generally, several strictures develop, and the series of strictures leads to chronic, high-grade obstruction that presents as postprandial cramping, nausea and vomiting. [22] This condition can progress to complete obstruction (a closed loop) a case in which surgery is mandatory. In jejunoileal obstruction, multiple tight strictures are often present, transforming the bowel into alternating saccular segments and tight strictures. This pathology does not simply cause classic obstructive symptoms. The stagnation that occurs in these saccular segments can lead to bacterial overgrowth, leading to diarrhea, malabsorption and nutrient deficiency as well. [22]

Surgical intervention is warranted when medical management fails, when the obstruction becomes complete, or when acute sepsis develops. Historically, resection was the mainstay of treatment, but strictureplasty is now the preferred operative approach for jejunoileal obstruction in non-emergent operations. In fact, recent data demonstrates that strictureplasty is safe even for grossly diseased intestine. While there remains a risk of necessity for reoperation, recurrent disease is most often away from the site of strictureplasty. [16, 22-24] Furthermore, relative to resection, patients treated with strictureplasty have fewer complications. [25] Therefore, when feasible, strictureplasty should be performed in jejunoileal stricturing Crohn's disease. The surgical approach to strictureplasty is discussed in detail in this chapter.

Figure 2. Construction Kono-S anastomosis. Adapted from Fichera A, et al., (2012) *Journal of gastrointestinal surgery*: official journal of the Society for Surgery of the Alimentary Tract 16:1412-1416.

Strictureplasty is not always feasible in the elective treatment of obstructive disease. If there is excessive tension due to rigid thickened bowel segments, multiple strictures within a short segment, or suspicion of cancer at the stricture, a segmental resection is indicated. [16] While primary re-anastomosis may be indicated for jejunoileal obstructive disease, the superiority of anastomotic configuration (i.e., end-to-side, side-to-side, end-to-end,) has not been well established. Many surgeons opt to create a generous anastomosis, with the belief that a larger initial lumen may lengthen the interval to clinical symptoms should further stricturing occur.

Kono and colleagues have recently proposed a novel technique for primary re-anastomosis after resection for Crohn's disease. [26] To attempt to reduce anastomotic recurrence of Crohn's disease after resection, a functional end-to-end handsewn anastomosis has been proposed, called the Kono-S anastomosis for small or large bowel (Figure 2). Once the bowel to be resected has been identified, that segment is divided transversely with a GIA stapler device, dividing the associated mesentery close to the bowel. Then, the corners of the staple lines are sutured together, and the staple lines are re-approximated in an interrupted fashion. On both sides of the newly re-apposed suture line, an anti-mesenteric longitudinal enterotomy is made. These two enterotomies are then re-approximated in two layers, allowing a large transverse lumen of 7-8 cm. [26, 27] Prospective data regarding recurrence rates of obstruction and active disease at the anastomotic site, however, is not yet sufficiently available, though this technique presents a promising alternative anastomosis that may prove more resistant to further obstruction due to a luminal widening. [26]

Terminal Ileal Obstruction

Chronic obstruction in the terminal ileal and ileocecal region is the primary indication for ileocecal operative intervention. [28] Traditionally, ileocecectomy with ileal-ascending colon anastomosis was performed for this condition, as many surgeons felt the intestinal walls in this region were not suitable for strictureplasty. The terminal ileum is often the most aggressive site of Crohn's disease. Bowel walls are often highly inflamed, with friable hemorrhagic mucosa and deep ulcerations. [29] As such, there has been a hesitancy to preserve the ileocecal region in these patients. In addition, the ileocecal valve itself may be involved in the inflammatory process, complicating local repair options.

However, strictureplasty of the terminal ileal and ileocecal region is possible. Strictureplasty, primarily of the Finney type (see section on Strictureplasty), has demonstrated no difference relative to ileocecectomy with respect to ten-year outcomes and clinical relapse of terminal ileitis. [29] Terminal ileal strictureplasty is becoming recognized as a viable alternative to segmental resection. Nonetheless, resection remains the technique of choice for many surgeons in the treatment of terminal ileal and ileocecal Crohn's disease.

For bowel resection, the primary considerations are the margin resection and anastomotic technique. In ileocecal resection for Crohn's disease, randomized controlled data have demonstrated no benefit with respect to recurrent rates between a limited resection (2cm margins from macroscopic disease) and an extended resection (12cm margins from macroscopic disease), several years postoperatively. [30] Therefore, radical resection is currently not recommended, particularly as bowel conservation is a fundamental component of small bowel surgery in these patients. [16]

There is limited data examining the superiority of stapled vs. hand-sewn, and end-to-end or side-to-side anastomosis after ileocecectomy in Crohn's disease. [31] Reports from the late

1990s retrospectively examined whether there was a difference in outcomes in stapled vs. sutured end-to-end anastomoses. These studies suggested that a stapled technique was associated with fewer complications and less recurrent disease at the anastomotic site. [32, 33] A 2004 study suggested that recurrent disease was less frequent in patients with stapled and hand-sewn side-to-side anastomoses relative to those constructed using stapled end-to-side technique. [34] McLeod, in 2009, published the first multicenter randomized controlled data assessing the influence of anastomotic type on recurrence of disease. It was found that disease recurrence rates were similar between end-to-end and side-to-side ileocolic anastomoses in patients who underwent ileocectomy for Crohn's disease. [35] Overall, the literature appears to favor stapling anastomoses over hand-sewing them. [36] However, until the emergence of high level, validated evidence, it is recommended that ileocolic anastomosis be constructed in a manner by which the surgeon is most comfortable.

Management of the Mesentery

In addition to anastomotic technique, consideration must be made of the surgical approach to the pathological changes in the mesentery. These include mesenteric fat growth (frequently encompassing the circumference of the bowel), diffuse inflammation with enlarged lymph nodes, and friable tissue. Energy devices often have difficulty forming a proper seal in this setting, as the vessels may fracture while the energy dissipates into the surrounding fatty coat.

Caution must be taken when clamping the inflamed mesentery of Crohn's disease patients. The surgeon should always be aware of the "corkscrew" vessels that penetrate near the bowel wall, as well as the presence of excess adipose tissue and pathologically enlarged lymph nodes, which still maintain their relationship to the underlying vasculature. [2] Mesentery can be managed by obtaining proximal control with atraumatic clamps, followed by ligation and control of remaining areas of bleeding. [31] Alternatively, serial, overlapping clamps can be used with a particular goal to prevent hematoma formation. [2]

Fistulizing Disease of the Small Bowel

A Crohn's disease fistula is an abnormal epithelialized connection between two organs. The interested reader is directed to an excellent review on the process of fistula formation in Crohn's disease, reported by Scharl and Rogler in 2014. [37] In active Crohn's disease, full thickness inflammation promotes the creation of pathologic fistulae either completely within the alimentary tract, or between a portion of the alimentary tract and an organ such as the skin, bladder or vagina. [38] Fistulae often develop at sites of active disease, however, one-fourth of fistulae in Crohn's patients form at anastomotic sites from previous bowel resection. [38] One of the most common complications of Crohn's disease, fistula formation occurs in 30-40% of patients. Over half of Crohn's fistulae are located in the perianal region. Approximately 24% of Crohn's fistulae are entero-enteric, while enterocutaneous fistulae account for approximately 6%. [38, 39] Internal fistulae, those that form between two internal organs, can often remain subclinical. External fistulae, in which there is a fistulous tract with the skin, are easier to identify.

Enterocutaneous Fistulae

Enterocutaneous fistulae (ECF) in Crohn's disease can be a significant management challenge. These fistulae generally develop after a previous bowel resection, and are classically ileocutaneous. In the early postoperative setting, ECF can present 7-10 days postoperatively due to anastomotic breakdown. If an ECF presents in a delayed fashion, typically after two weeks postoperatively, it may be attributed to a previously contained anastomotic leak. [40] They are initially managed with skin care, as well as nutritional support. Sepsis is the most common cause of mortality from ECF.

A fistula is considered high-output if it expels over 500 mLs per 24 hours, and in these cases, supplemental parenteral nutrition is often needed to avoid malnutrition. Multiple methods are used to reduce fistula output, including restriction of hypo-osmolar fluids, consumption of electrolytes with high concentrations of glucose and sodium, anti-secretory agents (*e.g.*, proton pump inhibitors, octreotide) and anti-motility agents (*e.g.*, loperamide). [38] ECF may close spontaneously or with the assistance of anti-secretory medications, however, treatment is often surgical. If spontaneous closure is not observed two months from diagnosis, surgical planning is then considered for a formal ECF resection.

Prior to surgical treatment of ECF, it is imperative that the patient is nutritionally optimized, managed with skin care and has intestinal anatomy defined. Classically, the best preoperative study performed prior to ECF resection was an upper GI contrast study with small bowel follow-through. However, this has largely been supplanted by CT imaging. With concerns over malignancy due to cumulative doses of radiation, some centers have moved to magnetic resonance enterography as the imaging of choice. The cost and lack of universal availability of this modality have limited its widespread adoption.

While not a complication of Crohn's disease *per se*, peri-ileostomy cutaneous fistulae can form after the initial ECF resection. Early postoperative peri-stomal fistulae develop due to excess tension placed on sutures between the abdominal fascia and bowel serosa, leading to bowel injury and subsequent fistulization with the skin. This complication begets another operation in which the ileostomy must be further exteriorized and a second stoma allowed to mature. [40] Fistulizing Crohn's disease may develop in the stoma; however, a fistula that develops may represent disease relapse rather than a technical misadventure. In contrast to perianal fistulae removal, in which there are multiple surgical techniques, ECF are generally removed via an abdominal incision, and excision of the fistulized segments of the small intestine. Often, temporary fecal diversion is performed with an ileostomy. [40]

Internal Fistulae

In Crohn's disease, a segment of the small bowel, upon becoming inflamed, can form an inflammatory adhesion and ultimately fistulize with another segment of bowel. The ileum is the most common site of active inflammation in the small bowel, and it is therefore by far the most common segment of small bowel involved in internal fistulae formation. Most frequently, the target organ for fistulization is the sigmoid colon, however, ileocecal fistulae and ileoenteric fistulae are common as well. Small bowel fistula formation can occur without ileal involvement as well, although this is far more rare. Gastrocolic and duodenocolic fistulae have been reported in small case series. [41]

Enteroenteric fistula, in which an inflamed portion of small bowel (generally ileum) fistulizes with additional small bowel, is often observed as well, as it was the most frequent fistula observed in a recently reported cohort of Japanese Crohn's disease patients. [42] In

addition, the small bowel can internally fistulize with a solid organ outside of the alimentary tract. In up to 8% of Crohn's disease patients, fistulae between bowel and the urinary system (ureter and bladder) can form spontaneously. With involvement in 64% of cases, the ileum is the most common segment of bowel involved in these fistulae. [41, 43]

Diagnosis of Small Bowel Fistula

Since they are often subclinical, internal fistulae of the small bowel can develop and progress without overt signs and symptoms. Typically, it is only late in the process when septic or obstructive symptoms necessitate diagnostic imaging. [40] The most common presenting symptoms for internal fistulae involving the small bowel are abdominal pain and diarrhea, although fever from abscess formation is seen as well. In one classic series of patients with fistulizing Crohn's disease, while most fistulae are diagnosed radiographically, up to ¼ of them are diagnosed intraoperatively, or on pathologic examination of the resected specimen. [44] In principle, fistulae can be diagnosed through a variety of means. Cross-sectional imaging (CT or MRI) or contrast studies will illustrate a fistula. In practice, the severe inflammation present often masks the small aperture of the fistula, and it may only be diagnosed intraoperatively.

Enterovesical fistulae in Crohn's disease are almost always ileovesical. Both urinary and gastrointestinal symptoms may bring attention to the diagnosis, perhaps even as the first clinical manifestation of the patient's Crohn's disease. Reported in 50-70% of patients with enterovesical fistulae, pneumaturia is the most common presenting symptom. Although pneumaturia may be an uncommon clinical sign, it is pathognomonic for this disorder.

Dysuria, fecaluria, suprapubic pain and recurrent urinary tract infections (UTI), generally due to *Escherichia coli*, are common symptoms as well. When suspected, diagnostic confirmation of the fistula is necessary, particularly for surgical planning. There are a variety of imaging techniques used in the case of a suspected enterovesical fistula. [45] These include cystoscopy, colonoscopy, the "poppy seed" test, transabdominal ultrasonography, computerized tomography, magnetic resonance imaging, barium enema, and a cystogram. In the poppy seed test, a few grams of poppy seeds are ingested orally. If there is a significant fistula, then the seeds pass through and are visible in the urine.

Although each modality has its own advantages and disadvantages, Golabek proposed an optimized diagnostic imaging algorithm after a best evidence examination of the literature. Once clinically suspected, both transabdominal ultrasound and the "Poppy seed" test are performed. If still suspected, CT/MRI imaging and cystoscopy with biopsy are undertaken. [46] Sigmoidoscopy may demonstrate the enteral side of the fistula; cystoscopy can show the bladder side. If the presence of an enterovesical fistula is confirmed after this workup, a management plan can then be initiated.

Management of Small Bowel Fistula

An Internal fistula involving the ileum or other small bowel region does not represent an indication for surgery; rather, a deleterious sequela from the fistula must be present.

The first indication is the creation of a bypass between segments of bowel due to the fistulous tract. If large enough, the disuse of that segment of bowel can lead to malabsorption, diarrhea, malnutrition and bacterial overgrowth. [39] Second, an internal fistula can exteriorize, becoming enterocutaneous in nature. Due to the high risk of malnutrition and septic complications, this is an indication for eventual surgical treatment. [40] Finally, the

development of a fistula can lead to abscesses in the abdomen which have the potential to cause obstruction.

Medical therapy can be used as a first line treatment of non-acute small bowel fistulous Crohn's disease, however, its failure to control the development of symptoms or abscess development from the fistula represents an indication for surgery. [39] While isolated enteroenteric fistulae can generally be managed nonsurgically, 40% of patients require surgery by one year, and an additional 33% within 9 years. [2] In surgical repair of internal fistulae involving the small bowel, the inflamed segment (usually ileal) is excised with either diversion or primary re-anastomosis. When the small bowel segment fistulizes with the sigmoid, it is often the practice of surgeons to close the fistulous opening in the sigmoid rather than resecting it. [45] Primary repair of the sigmoid is indicated if there is minimal inflammation of the colon. It is worth paying scrupulous attention to the character of the sigmoid colon, as suturing inflamed bowel may lead to a high rate of failure with subsequent leak, abscess, or sepsis.

Enterovesical fistulae due to Crohn's disease require prompt evaluation and management, due to the potential development of recurrent UTI and urosepsis. Once recognized, the first line of management is often medical. Consistent with general management of Crohn's disease, treatment with sulfasalazine, corticosteroids, 6-mercaptopurine and antibiotics such as metronizadole is often used. [47] In addition, bowel rest with total parenteral nutrition as well as ureteral catheter drainage is recommended for conservative management.

As there is scarce data on its efficacy, agents including TNF-alpha monoclonal antibodies should be reserved for second line medical treatment of enterovesical fistulae. [46] The goal of medical therapy is to reduce inflammation while preventing recurrent UTIs, allowing for the fistula tract to heal. Often, symptoms persist or recur, necessitating a surgical repair of the enterovesical fistula.

The goal of operative management of enterovesical fistulae is to resect the involved small bowel segment, and then performing an enteroenteric re-anastomosis. In addition, the hole in the bladder is closed. This repair may be endoscopic, open, or laparoscopic.

Laparoscopic repair of ileovesical fistula is currently the most frequent approach. [45] In the majority of cases, the resection can be done with a primary re-anastomosis of bowel segments. The bowel is bluntly dissected of the bladder wall. The bladder is then infused with a methylene blue solution via a Foley catheter if the hole is not clearly visible. Once identified, the vesical injury is then oversewed in one or two layers. Although some cystotomies have been left to heal spontaneously once divided from the fistula, it is our practice to attempt primary closure. [46] Some authors have advocated interposing an omental flap between the bladder and bowel, as the high vascularity may promote healing, however, high-level evidence for this technique still lacks. [46, 48]

In turning the attention to the bowel, the fistulous segment should be resected. If deemed feasible, primary reanastomosis should be attempted. A two-stage procedure is recommended in cases where the pathology or operation led to gross contamination of the abdomen with bowel contents, or a large abdominopelvic abscess was noted. [46] A temporary diverting ileostomy can be constructed, with closure of the colon (Hartmann's pouch), and re-anastomosis can be undertaken at a later date. While definitive surgical management of enterovesical fistulae is often quite successful, there is a risk of recurrence, in addition to other postoperative complications including abscess formation, enterocutaneous fistula development at the anastomotic site and anastomotic failure.

Anti-TNF Alpha Biologic Therapy

An integral component of the medical treatment of fistulizing Crohn's disease is the use of chimeric monoclonal antibodies, or human monoclonal antibodies against tumor necrosis factor alpha (TNF-alpha). The best known in this class are infliximab or adalimumab, and are reviewed. Briefly, TNF-alpha is a proinflammatory cytokine implicated in the pathogenesis of Crohn's disease.

In 2002, the ACCENT I trial demonstrated that intermittent infliximab infusion therapy maintained remission of Crohn's disease for the duration of the study (54 weeks), and allowed patients to discontinue corticosteroid use. [49] In 2004, the ACCENT II trial showed that infliximab infusion promoted and maintained closure of externally draining fistulae in Crohn's disease, with an acceptable safety profile. [50] This led to FDA approval of infliximab for the treatment of fistulizing Crohn's disease, and its clinical use has since been extended to treat various other manifestations.

The formation of fistulae is a consequence of the transmural inflammation unique to Crohn's disease. It is most prevalent and symptomatic in the perianal region. However, the small bowel is often involved as well. These fistulae require prompt management when they are cutaneous, or with another solid organ such as the bladder. However, fistulae between two segments of bowel, especially when in close proximity, can often be clinically monitored for symptomatology before surgical management.

There is little evidence that supports the use of anti-TNF therapy to treat fistulae involving the small bowel. Its use as a maintenance agent after a bowel resection is not clear as well; recent data demonstrates that infliximab therapy reduces the tensile strength of small bowel anastomoses in a rabbit model. [51] Generally, in fistulizing disease involving an internal fistula in the bowel, the first line treatment is surgery once it becomes symptomatic, while no specific treatment is indicated in asymptomatic cases. [45] In the case of enterovesical fistulae, there is no consensus on the use of anti-TNF therapy at this time.

Perforating Disease of the Small Bowel

Perforating Crohn's disease represents one of the primary phenotypes seen at diagnosis. The perforating phenotype includes symptomatic sequelae of bowel microperforations due to chronic inflammation, including fistulae or abscess. [52] Crohn's disease most often presents as obstruction, however, 50-60% of these patients are noted to have concomitant perforating disease at the time of surgery, and can add additional morbidity to the operation. [14] Notably, a 2013 study by Bellolio, reported that in patients undergoing ileocolic resection for Crohn's disease, those with perforating disease documented either preoperatively or intraoperatively required a more complex procedure, had a longer inpatient stay and were more likely to require a temporary ileostomy. [53]

The presence of perforating disease as the presenting phenotype has been shown to portend more frequent future abdominal operations, faster clinical symptomatic recurrence, and a higher immunosuppression requirement. [52] A suggested algorithm for the management of perforating Crohn's disease is illustrated in Figure 3.

Figure 3. A suggested management algorithm for perforation of the small bowel, adapted in part from Feagins LA, et al., (2011) *Clinical gastroenterology and hepatology*: the official clinical practice journal of the American Gastroenterological Association 9:842-850.

Abscess

Due to the transmural nature of Crohn's disease, one of the most common complications is development of intraabdominal abscess. Abscesses occur in 10-30% of Crohn's disease patients, and are most common between the ages of 20-30. [54, 55] Often, abscesses in Crohn's disease are formed at sites of prior bowel anastomoses. However, as many as 50% of abscesses in Crohn's patients are spontaneous, and form due to microperforations in diseased segments of bowel, usually in the ileocecal region. [55]

Several mechanisms have been proposed for abscess development. The first, and most common, involves transmural inflammation with fistulization to contiguous tissues, allowing for the direct spread of pathogenic bacteria. Second, diseased bowel can disseminate bacteria hematogenously, leading to intra-abdominal seeding. Finally, at the time of operation, peritoneal contamination of the bowel can lead to a complicating postoperative abscess. [56] The complex interactions between the bacteria and host lead to accumulation of neutrophils and the fibrin encasement of the abscess. The abscesses are generally polymicrobial, with *Escherichia coli* and *Enterococcus* as the most commonly isolated aerobes, and *Bacteroidis fragilis* and *Peptostreptococcus* as the most common anaerobes. [57]

The diagnosis of abscess is generally suspected in a patient with Crohn's disease who presents with fever or a new abdominal mass. Radiologic diagnosis is often confirmed with CT or MRI, though ultrasound is a reasonable diagnostic modality for superficial abscesses. Associated complications such as fistulae and stricture are often present, and can be assessed

by using an enterography protocol with the imaging, requiring the patient to consume oral contrast. MR enterography has been shown to be superior to CT enterography in one study, however, either modality provides valuable diagnostic information that can be used to guide management. Nonetheless, approximately 10% of abscesses remain clinically unsuspected, and are diagnosed at laparotomy for refractory disease. [54]

Classically, these abscesses required surgical drainage; however, trends in management have shifted toward the use of medical management alone, or percutaneous drainage. [57, 58] Over the past two decades, multiple studies have been performed examining the success of the several strategies of management of abscesses due to Crohn's disease. In addition to the abscess, the management of immunosuppressive therapy in the face of a septic complication presents a challenge. In theory, the clinician wants to pursue mutually exclusive goals: to preserve immune function to deal with infection, but also suppress the immune response to minimize intestinal inflammation. Usually, in the acute setting, the management of infection trumps the management of inflammation.

After assessment of studies examining the success of percutaneous drainage, Feagins proposed an algorithm for the management of intra-abdominal abscesses in patients with Crohn's disease (Figure 3). [57] Initial management of a spontaneous abscess, regardless of size, location, immunosuppression regimen or associated fistula, involves treatment with a broad-spectrum antibiotic regimen. Appropriate regimens include ticarcillin-clavulanate, ertapenem or moxifloxacin as monotherapy, or dual therapy with metronidazole and a fluoroquinolone (ciprofloxacin or levofloxacin) or an appropriate cephalosporin (i.e. cefazolin, ceftriaxone or cefuroxime). After institution of treatment with antibiotics, an abscess <3 cm can be observed for a short course, with a recommended repeat imaging study 4-6 weeks after initial diagnosis assuming no clinical deterioration. For abscesses >3 cm, or those with an associated fistula or on steroids, percutaneous drainage under radiologic guidance is indicated. If the abscess persists, a resection of the offending bowel region is indicated. If the abscess resolves, immunosuppression therapy can be safely resumed, though a surgical procedure will eventually be required for most patients. [57] There are few simple risk factors that predict the eventual need for operative intervention, but the duration and severity of symptoms typically give some indication of the success of purely medical management.

According to a recent report from the Nationwide Inpatient Sample, of 3,296 hospitalizations for intraabdominal abscesses in patients with Crohn's Disease in 2007, approximately 39% were treated medically, 29% with percutaneous drainage and 32% with surgery, representing a greater than fourfold increase in the use of percutaneous drainage since 1998. [58] Percutaneous abscess drainage is typically performed by interventional radiologists, and can be done under ultrasonographic, CT or fluoroscopic guidance. For typical abscesses, catheter sizes placed in the cavity are between 8 and 16 French, and generally require daily flushing with saline for maintain patency. In clinically improving patients, catheters can be removed when drainage is between 10-20 mL/d, however, if there are persistent signs and symptoms of infection, reimaging may be indicated to assess the placement of the catheter while looking for another potential focus of infection. Conversely, persistently high-output (>50 mL/day) from a percutaneous drain may indicate a contrast study through the catheter. Upon injection of the catheter with contrast, the small bowel can then be assessed for fistulization using X-ray technology. [59]

Percutaneous drainage has a very high success rate, particularly when there is not an associated fistula. Although delayed interval resection of the diseased segment is often required, an initial percutaneous approach is more successful in allowing for a primary re-anastomosis at the time of surgery, rather than temporary diversion, often required in open surgical drainage due to the presence of an infected field or need for perioperative steroids, compromising an anastomosis. [5, 57] Repeated studies have demonstrated that an interval resection following percutaneous drainage allows for an easier operation, with increased likelihood of primary re-anastomosis. [60, 61] Furthermore, Gutierrez demonstrated that two-thirds of abscesses treated percutaneously may not require surgery for at least one year. [56] Though typically reserved for cases not amenable or refractory to percutaneous drainage, an abscess still may be drained surgically. This operation involves thorough irrigation and debridement of the abscess cavity, followed by an en-bloc bowel resection. [57] However, if the abscess is recurrent and the patient is relatively well, a repeated attempt at percutaneous drainage is often performed, although studies assessing optimal management of recurrent spontaneous abscess in Crohn's disease are lacking.

Free Perforation

The most morbid presentation of perforating disease is due to a free perforation into the abdominal cavity. Spontaneous free perforations of the small intestine can be caused by many conditions, including trauma, infections, neoplasms, drugs, vascular disease or, as with Crohn's disease, immune-mediated or inflammatory conditions. [62] Unlike an abscess, which is walled off or contained due to a retroperitoneal location or a closed space, a free perforation usually presents with generalized peritonitis and requires emergent surgical intervention. Fortunately, in Crohn's disease, free perforation is quite rare, estimated to be less than 2%, though higher in Asian populations. [62, 63] The most common location for free perforation is in the ileum, though jejunal and duodenal perforations are also seen. Importantly, they may herald the presence of a Crohn's disease-induced neoplasm such as an adenocarcinoma or lymphoma. [62]

In a stable patient with suspected free perforation, obtaining a plain film of the abdomen is performed concomitantly with resuscitation and initiation of broad spectrum antibiotics. However, the lack of pneumoperitoneum on plain film should not exclude free perforation. Free air is only present in 20% of perforations in Crohn's disease patients, and this percentage may be even lower in ileal disease. [64] The patient is then promptly taken to the operating room for emergent exploration. After thorough examination of the small bowel, resection is performed in almost all cases of perforated jejunoileal disease, followed by primary re-anastomosis or construction of a temporary ileostomy, and thorough irrigation of the abdomen. [62, 65] In the rarer case of a gastroduodenal perforation, debridement and primary repair is recommended. [64]

The choice of diversion has traditionally been a function of the location of perforation, the stability of the patient, and the length of time since presentation. Specifically, the lower in the GI tract toward the rectum, the worse hemodynamic parameters, and the longer the timeline, should all prompt the surgeon to consider diverting ileostomy. In extreme cases, resection without anastomosis, leaving the GI tract in discontinuity with temporary abdominal closure, may be prudent. In these cases, return to the operating room for definitive anastomosis or stoma formation should follow the index operation within 48 hours.

OPERATIVE CONSIDERATIONS AND TECHNIQUE

General

In any Crohn's operation, the full length of the small bowel should be examined and described in the operative note. As it is a transmural process, the extent of Crohn's disease is defined by visual inspection of the bowel. Palpation of the mesenteric margin of the bowel wall is another key indicator of the extent of disease: once the margin is easily palpable, normal intestine has been reached. [2]

Resection

The first step to resection is to identify the extent of disease using radiographic and tactile guidance. It is unnecessary to remove bowel to negative micro- or macroscopic margins. For example, there is no need to resect areas of aphthous ulcers on otherwise healthy mucosa. [2] As alluded to previously, following the resection, a stapled anastomosis has a slightly less recurrence rate than a hand-sewn approach. [36] A paper by He supports this approach, and also advocates for a side-to-side anastomosis based on results from their meta-analysis. [66] The side-to-side anastomosis results in greater luminal width of the bowel. Finally, because of the recurrent nature of the disease, the surgeon should measure and document the extent of small intestine resected.

Not all patients benefit from an immediate anastomosis; as many as 20% will require a temporary ileostomy following ileocecal resection. [2] Common scenarios that require this approach include patients with poor nutritional status, chronic steroid therapy, sepsis, and the presence of an enterocutaneous fistula. [2] There is no literature to suggest any benefit to choosing either a loop or end ileostomy in these cases, however recent data suggests that anastomotic complications can be reduced by performance of a split-stoma in these "high-risk" patients that have at least two of the aforementioned factors. [67] A split-stoma involves exteriorization of both free ends of bowel after resection, with delayed re-anastomosis. Diversion is beneficial because it allows time for treatment of the underlying nutritional deficiency or heightened state of inflammation. Additionally, there is a growing body of evidence to suggest that fecal diversion, in and of itself, is associated with a lower risk of recurrence. [35] The mechanism is not entirely understood but is thought to be related to the integrity (or lack thereof in active Crohn's patients) of the intestinal mucosa as well as through a lack of fecal stasis in a narrow anastomosis. [35, 68-70]

Strictureplasty

The majority of patients (70-90%) with small bowel Crohn's Disease will require an operation at some point in their clinical course. [71] Patients with acute perforation, or those with focal disease, are primarily candidates for segmental resection. Generally, 40-50% resection of small bowel length is well tolerated, less if the ileocecal valve is not left intact.

[72] However, it may be those with medically refractory disease, or those with poor compliance, who are at risk for short gut syndrome.

Short gut syndrome is a functional entity, and there is no specific length of bowel that serves as a reliable threshold to predict the need for supplemental parenteral nutrition. However, short gut syndrome typically occurs in adults with fewer than 200 cm of intestine, and can be a significant problem in the Crohn's population. [73] When there is too little small bowel, malabsorption of both micronutrients and macronutrients can result. Ileal resection can rapidly lead to large fluid losses, and inability to absorb certain nutrients such as vitamin B₁₂. Jejunal resections, while generally better tolerated, can also lead to nutrient deficiencies. [72]

Additionally, extensive loss of small bowel length can cause a hormonal imbalance. Notably, the negative feedback mechanism for gastrin generation is removed leading to hypergastrinemic peptic ulcer disease and gastroesophageal reflux. [74] Short gut syndrome, therefore, necessitates close monitoring of nutritional status, frequent supplementation and carries the potential for harmful systemic sequelae, including a decreased life expectancy. [75] As such, when feasible, minimization of small bowel resection is advantageous. The strictureplasty is such a surgical technique, one in which one or multiple small bowel strictures are surgically opened, rather than resected, presenting an alternative, bowel-preserving operation for patients with a history of segmental resection. [76]

For non-phlegmanous small bowel Crohn's disease causing fibrotic strictures with symptomatic obstruction, the strictureplasty is the current treatment of choice. [77] The strictureplasty was first described by Katariya in 1977, in which a small case series of nine patients with obstructing tubercular strictures who underwent the procedure was described. [78] Within the next several years, the procedure was adapted to patients with Crohn's Disease, and early results of patients with strictureplasty as an alternative to bowel resection in small bowel disease were promising. The first report of strictureplasty for Crohn's Disease of the small bowel, reported by Lee, examined nine patients with chronic intestinal obstruction, as diagnosed by barium enema or enteroclysis. Using strictureplasty as one of three methods of relief of obstruction (minimal resections and short-segment bypasses were also used), no major complications were observed yet a lasting benefit was realized in terms of weight gain up to three years postoperatively. [79] Suddenly, the strictureplasty for small bowel Crohn's Disease gained favor as a safe and effective alternative for obstructing small bowel lesions. The procedure has developed such that there are several variations in surgical technique, dependent primarily on stricture length. These techniques are the Heineke-Mikulicz, Finney, Jaboulay and Michelassi, and will be described further.

Indications for Strictureplasty

The use of strictureplasty has expanded throughout the last two decades. Initially, the technique was used in only fibrotic structures. It is now a recognized procedure in patients with active disease. In 2006, Roy retrospectively examined 73 strictureplasties in 14 patients, in active, obstructive jejunoileal Crohn's disease, and found no worse recurrence and complication rates relative to limited resection. Despite the limited sample size and low level of evidence, the increased experience with, and improvement of the strictureplasty technique combined with the reported safety and efficacy profile, expanded the use of strictureplasty to patients with active, obliterative disease in addition to fibrotic lesions. [80]

In the 1980s, the strictureplasty technique was applied conservatively, as small (<10cm) strictures incised longitudinally and re-apposed transversely, a method analogous to the

Heinecke-Mikulicz technique for pyloroplasty. [81] However, the ability to successfully open longer strictures developed over the next 20 years, further expanding the indications for strictureplasty over resection in obstructive Crohn's disease. Not long after the Heinecke-Mikulicz technique was used, longer strictures (~12cm-25cm) were opened with the Finney procedure, a side-to-side anastomosis also previously used for pyloroplasty, with good results and few complications. Subsequently, in 1996, Michelassi described a side-to-side isoperistaltic strictureplasty method that is currently recommended for long-segment strictures (>25cm) or multiple closely-grouped short strictures. [82] In describing this technique, for which multiple modifications have since been made, the feasibility of strictureplasty as an alternative to segmental resection greatly increased. [77] Now, strictureplasty presents a viable option for patients with even long segment strictures and may thus prolong or prevent the necessity of enterectomy and subsequent development of symptomatic short gut syndrome.

There are several current indications for small bowel strictureplasty in Crohn's disease. Primarily, its use is indicated in patients with multiple strictures over a long segment of bowel, especially critical in patients with a history of prior bowel resections over >100 cm, or with short gut syndrome. In addition, patients with rapid recurrence of disease with obstruction, or strictures at previous anastomotic sites, particularly ileorectal or ileocolic, are also candidates for strictureplasty. [83, 84] Currently, evidence supports the use of strictureplasty primarily in the jejunal and ileal regions, as treatment of duodenal strictures has yet to be sufficiently investigated to recommend strictureplasty over bypass or resection, primarily due to the low prevalence of duodenal stricturing disease. [17, 84-86]

Contraindications

Performance of strictureplasty is contraindicated in certain instances. Preoperative malnutrition is a contraindication to strictureplasty, as it is with any procedure involving intestinal anastomoses. A serum albumin level <2.0 g/dL is reported as a cutoff for prohibitive malnutrition. [83] The presence of focal pathology such as phlegmon, fistula or perforation is a contraindication to strictureplasty throughout the length of the small bowel. Sepsis due to acute inflammation of the bowel is a sign that portends a poor ability of the bowel to hold suture, and strictureplasty in such a systemic inflammatory setting is highly likely to fail. Additional contraindications to strictureplasty include a stricture next to a site of planned resection and likelihood of tension on closure of strictureplasty. [83, 84]

Techniques of Strictureplasty

Heinecke-Mikulicz

The Heinecke-Mikulicz technique, described in 1888, was initially used for pyloroplasty. It popularized the concept of increasing the luminal diameter without resection, and remains a tenet of pyloroplasty in adults, primarily as a component of an acid-reducing operation. [87, 88] The procedure is most useful and safe for strictures under ten centimeters in length, and begins with determination of the location of stricture. This is generally done by palpation of the full length of small bowel, often with radiologic guidance. Once the operative site is identified, a full-thickness longitudinal incision through the bowel wall is made overlying the

strictured region, on the anti-mesenteric border (Figure 4). The incision is then closed transversely, generally using interrupted absorbable sutures. As the bowel wall is often edematous, stapling is not generally used for the transverse re-apposition. [83]

Figure 4. Heineke-Mikulicz strictureplasty. A: The stricture site is identified and a longitudinal incision made at the site. B: Stay sutures are used to distract the incision, and the incision is closed transversely in one or two layers. (Reprinted with permission from Cleveland Clinic Center for Medical Art and Photography; initially found in Hesham W, Kann BR (2013) *Clinics in colon and rectal surgery* 26:80-83).

Finney and Jaboulay

The Finney strictureplasty is the approach of choice for small bowel strictures between 10cm-25cm in length. In this approach, the strictured segment is folded in a U-configuration with a stay suture placed at the base of the “U” (Figure 5). An enterotomy is made, again on the antimesenteric aspect of bowel. Finally, the afferent and efferent limbs of the segment are sewn together in a side-to-side fashion using a full-thickness running absorbable suture for reapproximation of the posterior aspect, and an interrupted closure of the anterior aspect. [84] Alternatively, the anastomosis can be stapled. [89] The Jaboulay strictureplasty technique is similar to the Finney strictureplasty. In the Jaboulay technique, the “U” shape is created, but two separate longitudinal incisions are made. The enteroenterostomy is then fashioned in a side-to-side fashion effectively bypassing the primary strictured region. [83] There have been multiple techniques reported that include variations of the Finney and Jaboulay strictureplasties as well, however, for Crohn’s disease strictures under <25 cm, these two operations are the fundamental.

Figure 5. Finney type strictureplasty. A: The bowel is folded on itself at the region of the stricture. B: The side walls may be divided using a stapling device or via hand-sewn techniques. The enterotomy is closed via suture. (Reprinted with permission from Cleveland Clinic Center for Medical Art and Photography; initially found in Hesham W, Kann BR (2013) *Clinics in colon and rectal surgery* 26:80-83).

Michelassi

In 1996, Michelassi reported a technique for longer-segment (>25cm) strictureplasty in patients with stricturing disease of the small bowel due to Crohn's disease (Figure 6).

Figure 6. Michelassi (isoperistaltic, side-to-side) strictureplasty. (Reprinted with permission from Cleveland Clinic Center for Medical Art and Photography; initially found in Hesham W, Kann BR (2013) *Clinics in colon and rectal surgery* 26:80-83).

The eponymous technique can be used for a long continuous stricture, or for multiple strictures in close proximity, as an alternative to the Heinecke-Mikulicz, Finney and Jaboulay approaches. In this technique, the portion of diseased bowel is isolated with atraumatic bowel clamps, first dividing the associated mesentery at its midpoint. The proximal and distal loops are apposed in a side-to-side fashion, and a formal enteroenterostomy is made. At this step, stenotic areas of one loop should be opposed to dilated areas of the other loop to avoid persistent narrowing. Two layer closures of the enteroenterostomy and the blind ends are then made with non-absorbable sutures, in an interrupted fashion. This technique, or its variations, yields a side-to-side isoperistaltic strictuureplasty. [77]

Modifications have been made to these conventional approaches to strictuureplasty. These techniques have recently been summarized by Campbell. [90]

THE ROLE OF LAPAROSCOPY

Laparoscopic techniques have been used successfully in all aspects of management of Crohn's disease. Although they are reviewed extensively in other chapters, in skilled hands laparoscopic resection offers at least equivalent intestinal outcomes while minimizing trauma to the abdominal wall. Laparoscopic techniques have been applied to the small bowel since the 1990s, and several centers offer these advanced procedures to patients.

It should be noted that minimally invasive techniques represent a potential trap for the inexperienced surgeon. To begin with, the mesentery is deceptively thickened in many patients, and requires subtle changes in technique to ensure adequate hemostasis. Secondly, identification of inflamed segments of bowel becomes a visual exercise instead of a tactile one. Further, it is remarkably easy to traumatize the bowel while running the length laparoscopically, so that enterotomies may occur distant from the line of transection. Last, estimation of the length of bowel may be inaccurate in the laparoscopic setting due to the well-known phenomenon of errors inherent in the magnification afforded by the laparoscope.

A recent Cochrane review analyzed laparoscopic surgery for small bowel Crohn's disease. [91] Although only two randomized controlled trials were included, the reviewers found that there was a significant decrease in wound infection, intra-abdominal abscess, length of stay, and postoperative ileus with laparoscopic techniques. In addition, there was the suggestion that the risk of herniation was smaller in the laparoscopic group.

The safety of laparoscopic ileocecectomy, the most common laparoscopic small bowel operation in Crohn's disease patients,[92] was very recently evaluated by Antoniou as a best evidence topic. Five observational studies, three follow-up studies, two randomized trials and a meta-analysis were considered. [93] The report found that perioperative outcomes were similar to open surgery, and that the laparoscopic approach was safe for uncomplicated disease, assuming appropriate expertise of the surgeon. [93] On the other hand, leak rates of laparoscopic anastomoses may be higher, and there is little evidence that laparoscopic techniques lead to superior outcomes in the long-term.

There are other tangible benefits to the laparoscopic approach. For instance, some studies have shown that laparoscopy offered improved pulmonary function perioperatively. [94] There is potential for improved cosmesis and improved abdominal wall function that may restore the patient psychologically more than a generous midline laparotomy. In addition,

many patients will require multiple operations over their lifetimes, and it is advantageous to minimize trauma to the abdominal wall during each incursion. There is also decrease in the extent of adhesion formation, which is of critical importance to these patients who often face multiple operations. [95]

While laparoscopy for Crohn's disease offers is associated with decreased costs and hospital stay,[96] it comes at the expense of longer operative times. [97] Furthermore, patients with palpable masses or fistulizing disease are more likely to require intraoperative conversion, and may benefit from an initial open approach. [98] Laparoscopy is also feasible in patients with recurrent Crohn's disease, particularly so in non-fistulizing recurrent disease. [36, 99] In fact, single port laparoscopy is increasingly becoming a viable option for Crohn's disease operations. [100] It may be that the outcomes are dependent on surgeon experience, which we are often reluctant to admit as a specialty. Nonetheless, at this time, then, we advocate minimally invasive surgery as an initial approach for even patients with complex disease.

POSTOPERATIVE CONSIDERATIONS

There are few clear guidelines regarding the medical management of patients with Crohn's in the immediate postoperative period with exception to the use of immunosuppressive medication. Regarding general care, we advocate for the prompt resumption of enteral/parenteral nutrition as soon as the patient can tolerate. Because some patients may have lost a significant portion of their terminal ileum, they may be at risk for vitamin B₁₂ deficiency and bile malabsorption. B₁₂ stores are readily treated with oral supplementation, whereas bile-acids may necessitate sequestrants to prevent diarrhea. Fluid balance should also be attended to appropriately.

There is some general consensus concerning the administration of immunomodulatory medication. This can be subdivided into the use of these medications in the immediate perioperative period and over the long term as recurrence prevention. The latter will be discussed later in the chapter. 5-Aminosalicylic acid (5-ASA) drugs are eliminated renally with a short half-life and can be stopped a day before surgery and restarted postoperative day two. [101] Resumption of thiopurine therapy can commence on the second postoperative day providing that renal function is within normal limits. [101] There is mixed data regarding the use of biologics in the perioperative setting, however, it is notable that infliximab has a long half-life of 8-9.5 days. [101] Thus, it is reasonable to stop biologicals a month in advance of a planned surgery.

Postoperative surveillance is essential to monitor for either endoscopic or clinical recurrence, both of which will be outlined in the following section. The current paradigm is that endoscopic recurrence is the first manifestation of recurrent Crohn's disease, though not all endoscopic disease manifests clinically. [102] To monitor for endoscopic recurrence, the standard of care is to perform follow-up endoscopy one-year postoperatively. De Cruz showed that "endoscopically targeted therapy," with appropriate escalation of treatment if there were identifiable areas of recurrence at 6 month endoscopy, resulted in superior outcomes to the standard of care. [102-104]

OUTCOMES AND RECURRENT DISEASE

Recurrent Crohn's disease can be stratified into endoscopic recurrence or clinical recurrence. Endoscopic recurrence is disappointingly common on routine follow-up endoscopy, most often occurs within one year postoperatively, and is a risk factor for clinical recurrence. [105] Endoscopic recurrence after ileocecal surgery has been reported to be 79% at 1-3 years post-ileocectomy, and can be characterized the Rutgeerts scoring system, a measure of severity of endoscopic lesions. [106, 107] A score of 0 reflects no lesions, 1 reflects <5 aphthous ulcers, and a spectrum of inflammatory lesions continues up to a score of 4, reflecting diffuse inflammation with large ulcers, nodules and narrowing. Generally, a score of 1 or greater indicates endoscopic recurrence. [108, 109]

Clinical recurrence can be broadly defined as the recrudescence of severe symptoms after a primary operation, generally a resection. It can also be quantified by the Crohn's disease activity index (CDAI), the most popular of the scores used to quantify clinical severity of disease. This index is calculated from eight patient variables, including stool number and quality, abdominal pain severity, daily well-being scores, extraintestinal symptoms, antidiarrheal regimen, presence of an abnormal mass, hematocrit and body weight. [110] A CDAI>150 is taken to indicate recurrent disease. [109, 110] Clinical recurrence rates in the absence of treatment are estimated at 10-30% during the first year postoperatively, and in excess of 60% in the first decade postoperatively. [105]

Reoperations for recurrence have been approximated to be 10%-30% at 5 years, 20%-40% at 10 years and up to 60% at 20 years postoperatively. [16, 111] Reoperation, however, requires endoscopic confirmation, as the CDAI may be high in patients with symptoms or very low in patients with a severe recurrence, making postoperative endoscopy mandatory. Patients undergoing a first or second reoperation tend to have similar long-term clinical courses as those without an additional procedure. However, postoperative complications are increased, and length of stay is longer in reoperative surgery. [112] Patients with multiple reoperations will continue to experience more frequent recurrences of active disease, and have a shorter time until a permanent ileostomy is required. [36, 113] For obstructive disease, strictureplasties are often performed at the time of reoperation, if not the first operation, to preserve bowel. Cumulative reoperative rates after small bowel strictureplasty are between 22-45%, with a rate of re-stricture at the strictureplasty site estimated at 5-9%, higher at sites of ileocecal strictureplasties. [23, 36, 114-116]

There has been substantial research directed towards identifying risk factors that predispose one to recurrent disease in an attempt to stratify patients into either high or low risk categories. The most consistent risk factor in the literature is cigarette smoking, which consistently has demonstrated a significant association with recurrence. [102, 109, 117] In addition, evidence suggests that a history of prior resection, perforating disease, and myenteric plexitis are independent risk factors for recurrence. [102, 109, 117] Many other risk factors have been identified to predict recurrence in small studies, however, the results have either been ambiguous, or without external validation. These factors include gender, a positive family history of inflammatory bowel disease, a younger age of onset, a history of prior resection and the presence of small bowel or ileocecal disease over other locations. [104, 117]

With the identification of risk factors and the advent of stratification, patients are able to receive more tailored therapy. The first step for prevention of recurrent disease is smoking cessation. Medical therapies to prevent recurrence include drugs typically used in the treatment of Crohn's disease. However mesalamine and other similar 5-aminosalicylic (5-ASA) compounds provide only minor benefit in prevention across all risk categories. [102, 109, 117] Domenech suggested this benefit may be due to a delay in clinical symptoms, and not actually prevention of endoscopic recurrence. [117] It is generally accepted, however, that 5-ASA compounds are relatively well-tolerated and inexpensive, thus their use has been widespread. Thiopurines, including azathioprine and 6-mercaptopurine, are generally accepted to be first line therapy for low-risk patients. They exhibited a relative risk reduction for clinical recurrence vs. placebo of 0.59 (95% CI: 0.38-0.92) and endoscopic recurrence vs. placebo of 0.64 (95% CI: 0.44-0.92). [102] For high risk patients, anti-TNF agents are recommended as they had a greater relative risk reduction compared to placebo, with the recommendation to start them two to three weeks after surgery. [109, 117].

Not surprisingly, the most recent research suggests that anti-TNF agents are more efficacious than thiopurines in the prevention of recurrence. [103] Probiotics, interleukin-10, and steroids have all proven ineffective for postoperative prophylaxis. [102, 103, 117] There is some evidence that suggests nitroimidazole antibiotics, e.g. metronidazole, will decrease risk in the immediate postoperative setting when given for one month following the surgery, but side-effects and compliance prevent the widespread use of these as an adjunctive therapy. [102]

CONCLUSION

Crohn's disease is highly variable in its location and severity of presentation. Most patients, however, will require operative intervention during their clinical course. Small bowel involvement is quite common, particularly in the terminal ileum and cecum. While there are a variety of disease phenotypes and surgical indications, there remain guiding principles of surgical management of small bowel Crohn's disease. First, the goal of surgery is to make the operation as safe as possible. This involves directed preoperative imaging and optimization, as well as appropriate postoperative care and endoscopic followup. [16] Next, as serial operations are often necessary, conservation of bowel is paramount. [16] This can be accomplished by minimization of resection margins, or performance of strictureplasty for obstructing disease, a technique that can be accomplished in a variety of ways. Finally, the surgeon must recognize that unlike ulcerative colitis, Crohn's disease can not be treated with excision, rather, only complications and severe symptoms should be pursued operatively. As with any surgical procedure, the surgeon should be certain an operation will truly benefit the patient, and also consider whether a laparoscopic approach may be beneficial. [16]

²University of Maryland School of Medicine, Baltimore, MD, US

ABSTRACT

Crohn's disease frequently involves the colon. The majority of patients with colonic Crohn's disease will require surgical intervention at some point. The management of Crohn's colitis includes a careful assessment of the patient's response to medical therapy and the anatomy involved. Selection of treatment is based on preserving as much function and quality of life as possible. While surgery cannot cure Crohn's colitis, it can remove life-threatening complications and provide excellent symptom relief. Surgical options include proximal diversion, ileocectomy, segmental colectomy, total colectomy, proctocolectomy, and in select patients, ileal pouch-anal anastomosis. The choice of surgical treatment requires a thorough knowledge of currently evolving literature. This section will discuss the current state of evidence-based clinical practice in the surgical management of Crohn's colitis.

INTRODUCTION

Crohn's disease is an ulcerogenic, transmural, inflammatory bowel disease that can affect any portion of the gastrointestinal tract. Crohn's disease is most frequently found in the terminal ileum or ileocolic region (55%), with an additional approximately 20-30% of patients presenting with isolated colonic disease[1,2]. Colonic disease typically presents with abdominal pain, perianal complications, rectal bleeding, or extraintestinal manifestations.[3] As with Crohn's disease in general, the foundation of current treatment for colonic Crohn's disease is medical therapy with aminosalicylates, immunomodulators, biologic agents, and steroids, with surgery reserved for complications of the disease and failure of medical management.

As a whole, greater than 75% of Crohn's patients require surgery during their lifetime.[4,5] Symptomatic recurrence of Crohn's disease will occur within the first five years postoperatively in approximately 30 to 50% of patients, and in 50 to 80% within 10 years.[6] Reoperation can be expected in 40 to 50% of patients within 10 to 15 years.[7] Anatomic distribution of disease affects the rates of surgical intervention. Right-sided colonic disease or disease involving the terminal ileum accounts for 40% of patients undergoing surgery.[3]

The failure of medical management remains the leading indication for surgery in Crohn's patients.[4,5] Reasons for failure vary widely in patients from noncompliance, to intolerable side effects, to lack of response to the medical regimen. It is important that clinicians realize that surgical intervention is not a "failure", but rather, an opportunity to offer many patients a demonstrable improvement in their quality of life.[8-10] Surgery for Crohn's disease of the colon includes ileocolic resection, segmental colon resection, total colectomy, proctocolectomy, and proximal diversion. Complications of Crohn's disease and their associated surgical indications can be separated into acute and chronic categories.

INDICATIONS FOR SURGERY

Acute

Obstruction

Colonic obstruction in Crohn's disease is not uncommon, occurring in almost 17% of patients.[11] Strictures can occur throughout the colon and are due to fibrosis associated with repeated episodes of transmural inflammation. Over time, the wall thickens and becomes irreversibly scarred and fibrotic, with a progressively decreasing luminal diameter. Many strictures, including those at previous anastomotic sites, are responsive to endoscopic dilation.[12] However, up to 7% of colonic strictures in Crohn's patients may contain malignancy and should always be biopsied.[11,13] In the event of a positive biopsy, resection should follow established oncologic guidelines. In the absence of malignancy, many strictures can be treated conservatively, however frequent or severe obstructions should be managed with surgical intervention.

Hemorrhage

Hemorrhage occurs infrequently in Crohn's disease as compared to ulcerative colitis.[14] Patients may develop lower gastrointestinal bleeding, but it is usually associated with a separate complication, such as neoplasia or toxic megacolon. Initial management includes resuscitation with intravenous fluids, blood transfusion, correction of any coagulopathy, and attempts to identify the source of hemorrhage within the GI tract. Colonoscopy can be used if the hemorrhage is from a suspected colonic source. Angiography and nuclear medicine imaging may also play a role. The extent of resection is determined by successful identification of the bleeding source. In general, grossly affected colon should be resected, preserving as much future colorectal function as possible. In all, nearly 40% of patients with inflammatory bowel disease will require surgical resection to correct the hemorrhage.[15]

Abscess

Contained perforation leading to abscess or fistula complicates colonic Crohn's disease much more frequently than free perforation. Following initial resuscitation, additional treatment depends on the patient's response and clinical stability. Hemodynamically unstable patients and those with generalized peritonitis should undergo immediate surgery. For stable patients, percutaneous abscess drainage is typically undertaken.[16] In the past, most patients went on to receive surgical resection of the involved segment. However, a recent study showed similar rates of complications and abscess recurrence when medical and surgical treatment of Crohn's-related abdominal abscesses were compared.[17] The management of intra-abdominal septic complications of Crohn's disease will be discussed further in Section III.

Perforation

Although rare, perforation can occur in patients with Crohn's colitis and is an emergent indication for surgical intervention.[18] Perforation is most associated with small bowel disease with obstruction or abscess. In patients with colonic disease, perforation is usually seen complicating toxic colitis.[19,20] Toxic megacolon, or toxic colitis, is a life threatening complication of Crohn's disease. Diagnosis is made during a disease flare with the presence of colonic dilatation as well as two of the following: leukocytosis, tachycardia, or temperature greater than 38.6.[21] Initial management includes aggressive resuscitation, bowel rest and decompression, immunosuppressants, such as intravenous steroids, broad-spectrum antibiotics, and possibly nutritional support. Perforation or impending perforation, lack of improvement within 2-3 days of conservative management, clinical deterioration, and shock/sepsis are indications for immediate operative intervention. Surgery for toxic colitis usually consists of total abdominal colectomy with end ileostomy.

Chronic

Failure of Medical Therapy

Some complications that lead to the failure of medical management occur due to adverse effects of the immunosuppressive medications themselves. Long-term corticosteroid use can result in suppression of adrenal function, hypertension, osteoporosis, infections, including increased rates of abdominopelvic abscesses, hypokalemia, and hyperglycemia.[22] Corticosteroids should therefore never be used for maintenance of disease remission. Of the patients who receive corticosteroids for acute symptoms, 50% will develop steroid "dependent" or "resistant" Crohn's disease,[23] with higher rates of resistance seen in smokers and patients with colonic involvement.[24] Half of these patients will progress to resistance and require surgery within one year.[25] Other patients have continued or worsening symptoms despite escalation of medical therapy, which may include aminosalicylates, immunomodulators, and biologic agents.

Growth Retardation in Children

The metabolic consequences of Crohn's disease can be especially severe in the pediatric population. Growth retardation occurs in 15%-40% of children affected and may precede the

clinical diagnosis of Crohn's by several years.[26-28] Failure of growth is due to malabsorption, decreased caloric intake, and increased nutrient loss as a result of the disease's effect on the GI tract. Surgical intervention has been shown in retrospective series to improve growth velocity and pubertal development in patients with growth retardation.[29-31]

Malignant Transformation

As a pro-inflammatory disease, it is not surprising that patients with Crohn's disease have a higher incidence of several types of malignancy,[32] especially colorectal cancer.[33] When discovered, resectable malignancy remains an indication for surgical intervention. The extent of colonic resection required for Crohn's colitis patients with colorectal dysplasia or cancer is somewhat controversial and will be discussed later in this chapter.

Fistula

In patients with Crohn's disease, the colon is sometimes affected by fistula formation (Figure 1).[34] Overall, fistulization is predictive of higher lifetime relative risk (1.7) of receiving surgical treatment[3] and is independently associated with decreased time to surgery (HR, 3.44, 95% CI 2.33 to 5.08 vs inflammatory disease).[35] Given the transmural nature of Crohn's disease, fistulous communication with other bowel,[36] lung,[37] vagina,[38] bladder,[39] or skin[40] have been reported in patients where the colon is the primary site of inflammation. The colon may also be involved secondarily with fistulous communication arising from the stomach, duodenum, or small bowel.[40] Fistulizing disease is associated with increased postoperative complications, higher rate of conversion to open procedure, and higher incidence of postoperative fistula formation, of which enteroenteric is the most common.[41,42] Even with the development of anti-TNF agents, 75% of patients being treated for fistulizing Crohn's disease still require surgical intervention.[43]

Figure 1. Ileal-sigmoid fistula secondary to Crohn's disease.

SURGICAL ILEOCOLONIC DISEASE

Indications for Surgery

Ileocolonic disease is the most common presentation in Crohn's disease and the leading cause of surgical intervention. The preferred method of surgical treatment is resection of the

diseased bowel. Operation for ileocolonic Crohn's disease is indicated in any of the complications discussed above. The majority of patients with ileocolonic disease undergo surgery for either penetrating disease, which leads to fistula or abscess, or stricturing disease, which causes partial or complete obstruction and possibly perforation. Penetrating and stricturing disease can be a continuum of disease pathogenesis, where perforation arises in areas of transmural inflammation due to increased pressure produced by downstream stricture, especially at the ileocecal junction.[44]

Between 10%-30% of patients with Crohn's disease will develop an abdominal or pelvic abscess.[45] Microperforation of transmural ulcerations with or without fistula formation is the accepted pathogenesis of perforating Crohn's disease. Abscesses most frequently occur due to disease within the terminal ileum and cecum.[45,46] The preferred treatment of Crohn's-related abdominopelvic abscesses is with antibiotics and percutaneous drainage.[47,48] The timing of and need for definitive surgery has been debated in the literature. Most authors recommend controlling sepsis with the methods discussed above followed by subsequent elective surgery to resect the affected bowel. Gutierrez showed that one-third of patients who underwent successful percutaneous abscess drainage ultimately required surgery within one year's time.¹⁶ When managing Crohn's patients with intra-abdominal septic complications, a holistic review of the individual's disease course and a multidisciplinary approach to therapy is advocated.[46,49]

Stricturing disease is caused by chronic and severe inflammation of the bowel wall with up-regulation of extracellular matrix component deposition, including collagen and fibronectins, and mesenchymal cell expansion.[50] As with penetrating disease, the most common location for stricturing disease is the terminal ileum and ileocecal junction.[51] Despite improvement in most Crohn's disease metrics over the past few decades, stricturing disease has not decreased in incidence with the advancement of medical therapy.[52]

Minimally Invasive Ileocolic Resection

The last fifteen years have witnessed an increase in the use of laparoscopy following the publication of the first prospective randomized controlled trial comparing laparoscopic versus open surgical intervention.[53] Initial results indicated that laparoscopy results in fewer complications, a shorter length of hospital stay, and reduced time to pulmonary recovery. In 2006, a multi-institutional prospective randomized controlled trial by Maartense, showed a reduction in hospital stay and hospital costs, with similar results in quality of life and return to normal diet.[54] Both studies found no significant difference in rates of anastomotic leak, intra-abdominal abscess, and reoperation in the first 30 days. Although limited in their power, these initial studies provided the first evidence that the safety and efficacy of laparoscopy was comparable to that of open surgery.[2]

Further studies have replicated these initial results. Several meta-analyses comparing laparoscopic to open ileocolic resection found benefit to laparoscopy with respect to postoperative complications and morbidity,[55-57] length of hospital stay,[55,56,58] and return of bowel function[56-58] in the short term. These studies also demonstrated a significant increase in operative time for laparoscopy versus open surgery. Longer-term follow-up of these patients showed similar or lower rates of disease recurrence[56,57,59-61] and overall morbidity [56,57,60,62]. Bergamaschi also found a lower rate of bowel

obstruction at 5 years of follow-up after laparoscopic versus open ileocolic resection.[61] These authors concluded that experienced surgeons may offer the majority of patients laparoscopic intervention for ileocolic Crohn's disease.

More recently, several series have been published on the use of single incision laparoscopic surgery (SILS). Stewart published a series of six patients who underwent SILS for complicated ileocolic disease. These authors demonstrated no conversion to open, return of bowel function in 1.6 days, and hospital stay of 4.8 days, which all compares favorably to traditional laparoscopic techniques. A larger retrospective series of 20 patients who underwent SILS as compared to 20 individually matched traditional laparoscopy patients showed no difference in length of stay, postoperative pain, morbidity (ileus, wound infection, intrabdominal abscess), or conversion to open surgery.[63] The SILS group had a shorter operative time.

Methods of Anastomosis

Outcomes in laparoscopic bowel resection appear to be influenced by several factors. Smoking, perianal disease, presence of perforation, and surgical technique have all been associated with worse outcomes.[64] As a modifiable risk, interest in surgical technique has gained attention in the literature. McLeod found that anastomotic type (side-to-side versus end-to-end) did not affect disease recurrence in their multi-center randomized trial.[65] Ikeuchi found that stapled anastomosis delayed recurrence when compared to hand-sewn anastomosis.[66] A meta-analysis by Guo comparing the differences between side-to-side and end-to-end anastomoses demonstrated no significant difference between the two with respect to short-term complications or recurrence.[67] Their analysis did suggest that the stapled side-to-side anastomotic technique might improve outcome.

A recent meta-analysis looking at this question demonstrated that stapled side-to-side techniques do carry a lower risk of overall postoperative complications, anastomotic leak, recurrence, and reoperation for recurrence, when compared to hand sewn end-to-end anastomosis. Length of stay, mortality, and complications other than anastomotic leak were not significantly different. However, a variance in follow-up between the two groups, 34 months for the stapled anastomosis versus 92 months in the hand-sewn anastomosis, is a limitation.[68] A novel anti-mesenteric functional end-to-end anastomosis, or Kono-S anastomosis, has shown low rates of complications in short-term follow-up.[69,70] These studies suggest that side-to-side stapled anastomosis may provide a short-term benefit in complications and recurrence, however long-term comparative trials are needed.

CROHN'S DISEASE OF THE COLON

Isolated involvement of the colon in Crohn's is seen in one third of patients (Figure 2).[2] The common anatomic distributions within the colon are pancolonic involvement in about 30% of patients, left-sided disease in approximately 30% of patients, and segmental disease in 40% of patients.[3,71] Patients may present with abdominal pain, malnutrition, and hip or pelvic pain from abscess or fistula.[3,71] Indications for colonic resection include fulminant

colitis non-responsive to medical therapy, intolerable side effects of medical therapy, hemorrhage, obstruction, and abscess or fistula. Surgical options include subtotal colectomy with ileorectal anastomosis, total proctocolectomy, and segmental colectomy.

Recent literature suggests that isolated colonic Crohn's disease presents with pathologic and clinical characteristics, which differ from patients with other anatomic distributions of the disease. One study demonstrated that 81% of patients presenting with pancolitis suffered from isolated colonic disease. This study also showed a higher rate of extracolonic disease in patients undergoing segmental colonic resection.[72]

Hancock published results showing that patients with isolated colonic disease were more commonly female, non-smokers, and carriers of the DRB1*0103 allelic polymorphism as compared to patients without colonic involvement.[73] Recently, Soucy found that patients with isolated colonic Crohn's disease present later in life. Reproducing results of Hancock, they also demonstrated a shorter mean time before surgical intervention in these patients.[74] Interestingly, Soucy also described a subpopulation within the isolated colonic involvement group with 'ulcerative colitis-like Crohn's colitis', a disease entity which has been sparsely reported in the literature.[75,76] Patients with ulcerative colitis-like Crohn's colitis present at an earlier age, however have a less severe phenotype and fewer histologic characteristics of Crohn's disease compared to their standard Crohn's colitis counterparts. Outcomes appear otherwise similar.[74]

Toxic Colitis

Toxic colitis or toxic megacolon is the most severe form of Crohn's colitis, and a frequent cause of urgent surgical intervention. Similar to the more common toxic megacolon seen in ulcerative colitis, toxic megacolon due to Crohn's disease is initially treated with medical management, including aggressive resuscitation, antibiotics, and possibly immunosuppressive agents. Following adequate resuscitation, patients with perforation, uncontrolled bleeding, and those who clinically deteriorate should receive emergent surgical intervention.[77]

Figure 2. Severely inflamed transverse colon in a patient with Crohn's colitis.

Early operative management was with a loop ileostomy and “blowhole” transverse colostomy, as reported in 1970 by Turnbull.[78] However, this procedure was associated with high rates of mortality (71%) and complications, including ongoing severe bleeding.[79] The Turnbull procedure is therefore rarely performed presently, except in the most severely ill patients who are unable to tolerate longer operations.

Total proctocolectomy and subtotal colectomy with end ileostomy are the remaining options for surgical intervention. One study showed that in patients who received total proctocolectomy for toxic megacolon, complication and mortality rates were both 21%, whereas in those treated with subtotal colectomy with end ileostomy, the complication rate was 8% and the mortality rate was 6%[79]. The use of subtotal colectomy with end-ileostomy has greatly reduced the mortality of toxic colitis and remains the procedure of choice.

Segmental versus Subtotal Colectomy

Similar to that for small bowel disease, maintenance of colon function with bowel sparing techniques is the goal of current surgical treatment of colonic Crohn’s disease. Despite the eventual choice of procedure, the literature is clear that segmental colectomy only requires resection to grossly normal bowel.[80] The choice of surgical procedure is governed largely by the anatomical presentation of the disease. Fichera published a prospective series of patients comparing the surgical outcomes of segmental colectomy, total abdominal colectomy, and total proctocolectomy.[81] Clinical characteristics were the same for all groups, except the segmental colectomy patients were significantly younger. The authors found that patients with diffuse colonic involvement, distal colonic involvement, or multiple involved segments were significantly less likely to receive segmental colectomy. The literature has conflicting data regarding the rate of recurrence following the surgical options mentioned above. In Fichera’s study, segmental colectomy patients had a greater risk of recurrence than patients who received proctocolectomy, but not subtotal colectomy.[81] These results were confirmed in a large meta-analysis that compared segmental resection to subtotal colectomy with ileorectal anastomosis; no significant difference in incidence of surgical recurrence was found between groups.[82] A more recent single institution series also demonstrated that segmental colectomy was not an independent predictor of disease recurrence.[83]

There is some consensus that the speed of recurrence differs between surgical techniques. Fichera reported a significant difference in time to first recurrence between the three surgical groups, especially between segmental colectomy and total proctocolectomy. Tekkis similarly found that the segmental resection group presented with recurrence approximately 4 years earlier.

One important consideration concerning patient quality of life is the need for a permanent stoma following colectomy. In Fischera’s study, the need for permanent stoma was significantly higher in patients presenting with isolated distal colonic disease versus isolated proximal disease.[81] Kiran found no difference in stoma free survival between segmental colectomy (76.8%) and subtotal colectomy (84.2%) groups. Past perianal sepsis and the presence of multiple comorbidities did reduce stoma-free survival.[83] These studies support the conclusion that both segmental and subtotal colectomies are reasonable options for

treatment of Crohn's colitis when used in conjunction with careful patient selection and thorough review of patient disease course.

Colectomy for Dysplasia or Cancer

Proctocolectomy is the standard therapy for ulcerative colitis patients with colorectal dysplasia or cancer, based on literature demonstrating high rates of synchronous and metachronous disease.[84,85] The surgical management of dysplasia in patients with Crohn's colitis is largely extrapolated from ulcerative colitis data, given a lack of similar studies in patients with Crohn's disease. However, the presence of segmental disease as well as the lack of an ideal reconstructive option makes proctocolectomy a less obvious treatment choice in patients with Crohn's colitis.

Kiran et al. evaluated 50 patients who underwent colectomy for Crohn's colitis-associated dysplasia. 44% of patients who underwent total proctocolectomy or subtotal colectomy had multifocal dysplasia. Of those patients who had a colorectal cancer, 40% had dysplasia remote from the cancer site. The authors therefore recommended total proctocolectomy as the treatment of choice in good-risk patients.[86] Maser et al. found that 40% of patients who underwent segmental resection for colon cancer and 35% of patients who underwent subtotal colectomy for colon cancer developed metachronous cancer. 43% of patients who underwent segmental colectomy and 50% of patients who underwent subtotal colectomy for dysplasia developed a new dysplasia. They similarly concluded that total proctocolectomy should be considered in Crohn's patients with dysplasia or cancer due to high rates of metachronous disease.[87]

Based upon limited data, total proctocolectomy rather than subtotal or segmental colectomy should be strongly considered in Crohn's colitis patients with colorectal dysplasia or cancer.

DISTAL COLONIC DISEASE

The management of Crohn's disease affecting the distal colon is challenging. Patients with isolated distal disease are significantly more likely to require a permanent stoma than those with isolated proximal disease (54% vs 11%).[81] Patients with distal involvement are also significantly more likely to undergo a more extensive resection than those with more proximal disease patterns.

Surgical indications for distal resection are dependent on the extent of inflammation and anatomy involved. Total proctocolectomy and end ileostomy is indicated when patients present with diffuse and extensive colorectal disease. In those patients with rectal sparing (40%[88]), both total abdominal colectomy with ileorectal anastomosis and segmental resection can be considered. For patients with concomitant distal colonic and perianal Crohn's disease, surgical options include proctectomy with end-colostomy, proctocolectomy, and proximal diversion with or without segmental or subtotal colectomy.

Techniques in Crohn's Colitis with Rectal Sparing

Total Proctocolectomy

The management of Crohn's colitis with relative rectal sparing is a current area of controversy in the literature. In patients with Crohn's colitis, concomitant involvement of the rectum and anal canal must be considered when choosing treatment. Total proctocolectomy is the most appropriate option for patients with extensive colitis and refractory perianal disease, despite the presence of rectal sparing. This procedure involves the removal of all colonic, rectal and perianal disease and therefore affords the lowest rates of recurrence, reoperation, and need for medical therapy postoperatively.[81,89,90]

On the other hand, many patients undergoing surgery for Crohn's disease are relatively young, and the risk of pelvic nerve injury, including impact on sexual function and fertility, may not be considered acceptable.[89,91] Further, total proctocolectomy results in a permanent end ileostomy, which can negatively impact patient satisfaction and quality of life. As a result, high levels of patient resistance to this procedure are frequently encountered. In recent years, intersphincteric proctectomy is being used to avoid sexual dysfunction related to dissection near the hypogastric nerve plexus and also to reduce the rate of perineal wound complications.[92]

Total Abdominal Colectomy with Ileorectal Anastomosis

Total abdominal colectomy with ileorectal anastomosis is a further option in patients with rectal sparing. It is preferred for patients without perianal disease and for those whose perianal disease is mild. A series of 833 patients with Crohn's colitis demonstrated fairly high rates of symptomatic recurrence when subtotal colectomy with ileorectal anastomosis and segmental colon resection were compared with subtotal colectomy and proctocolectomy with ileostomy (58% and 47% versus 24% and 37%, respectively). On multivariate analysis, perianal disease, ileorectal anastomosis, and segment resection were independent risk factors for recurrence.[93] Andersson also found similar rates of re-resection following segmental versus subtotal colectomy for Crohn's colitis. However, segmental colectomy patients had the advantages of fewer loose stools, better anorectal function, and fewer symptoms overall.[94]

In contrast, a large meta-analysis examining 488 patients undergoing ileorectal anastomosis versus segmental colectomy showed that ileorectal anastomosis lead to lower rates of postoperative complications and permanent stoma creation. Those patients with multiple affected colonic segments were less likely to need re-operation when they underwent ileorectal anastomosis.[95]

Ileal Pouch-anal Anastomosis (IPAA)

Ileal pouch-anal anastomosis (IPAA) may be an option for very select patients with both ileal and anal sparing Crohn's disease. The more common setting for this procedure is in patients who carry a preoperative diagnosis of ulcerative colitis, and are subsequently diagnosed with Crohn's disease on final pathology. A study of 60 patients in this situation found that 35% developed disease recurrence, 40% reported issues with continence, and 12% ultimately required pouch excision.[96] Another study of 41 patients with ileal and rectal-sparing inflammation including 26 patients with a preoperative diagnosis of Crohn's disease, demonstrated a 10% rate of pouch excision, and a 35% incidence of serious complication,

including pouchitis, abscess, and fistula formation.[97] Many of these patients had improvement in symptoms with medical management, and therefore the authors concluded that IPAA is warranted in Crohn's patients meeting the criteria of ileal and anal sparing disease.

Several contemporaneous studies found that the outcomes of IPAA in Crohn's disease were not as favorable. One study published results showing that 56% of patients who underwent restorative proctocolectomy for Crohn's colitis required diversion or pouch excision compared to only 6% who had the procedure performed for ulcerative colitis.[98] Further, Bravemen found that of 32 patients diagnosed with Crohn's disease postoperatively from IPAA, 93% had significant complications, including fistula (63%), pouchitis (50%), and anal stricture (38%). Pouch excision or permanent diversion was required in 29% of patients.[99]

Finally, a meta-analysis of 10 studies, including 3103 patients who underwent restorative proctocolectomy for inflammatory colitis, Crohn's disease patients (n=225) had higher rates of incontinence, anastomotic strictures, and pouch failure.[100] In summary, ileoanal pouch construction remains controversial due to significant variance in the rate of complications (35% to 93%[96-100]) reported in the literature. Some studies have suggested better outcomes in those Crohn's colitis patients without perianal disease or small bowel involvement. Other investigators have not found any features predictive of outcome after an IPAA procedure.[99]

LAPAROSCOPIC TECHNIQUES IN CROHN'S COLITIS

Laparoscopic techniques have significantly improved the outcomes of patients undergoing colorectal surgery. There is an abundance of evidence showing advantages of laparoscopic colorectal surgery over open technique, including reduced length of hospital stay, decreased postoperative narcotic use, reduced wound complications, and earlier return of postoperative bowel function.[101-103] Laparoscopic colectomy was first reported in 1991.[104] Soon after, interest arose in the use of laparoscopy for the treatment of Crohn's disease, given the young age of Crohn's patients requiring surgery, the recurrent nature of the disease and therefore the high likelihood of subsequent reoperation, the high rates of complications, in particular wound infections, seen following traditional Crohn's surgery, and the debilitated state patients with Crohn's disease often present in. Laparoscopic colectomy followed behind laparoscopic ileocolic resection and early comparisons were favorable.[105]

One of the earliest studies examining the use of laparoscopy in Crohn's colitis was published in 2007. In this study, the authors compared 27 patients who underwent laparoscopic colectomy with matched controls.[106] They found significantly higher median operative times, comparable rates of blood loss, and similar postoperative complications. However, they also demonstrated shorter median length of stay and time to first bowel movement. When 30-day readmissions were included, laparoscopic surgery also led to significantly shorter overall length of stay.

One review of a prospectively collected database from a single institution evaluated 92 patients who underwent laparoscopy and hand-assisted laparoscopic surgery (HALS) for total, subtotal, or segmental colectomy. The authors reported a median operative time of 248

minutes and a mean postoperative length of stay of 5 days. The rate of any complication was 34%, and was predicted by perianal disease. The overall conversion rate was 16%, which was predicted by presence of small bowel disease. When the study patients were further subdivided into segmental colectomy and either total or subtotal colectomy, the segmental colectomy group was significantly less likely to have a complication. The authors concluded that laparoscopy was safe with “reasonable operative times, conversion rates, and excellent postoperative outcomes”.[107] A second prospective study of patients undergoing laparoscopic versus open colectomy demonstrated a shorter length of stay, earlier return of bowel function, less intraoperative blood loss, and fewer complications in the laparoscopic group. The conversion rate was 10.9%.[108] The literature-to-date supports these authors’ conclusion that laparoscopy is a safe and effective surgical option for patients with colonic Crohn’s disease.

Recurrent disease is a noteworthy challenge in the management of patients with Crohn’s. As the indications for laparoscopic intervention in colonic Crohn’s disease grow, its use in difficult recrudescence cases is expected. There are several studies available which have investigated the use of laparoscopy in recurrent disease with favorable results.[42,109] In a study of 26 patients who underwent mixed small and large bowel procedures, laparoscopic and open techniques were compared. The authors found similar rates of blood loss, operative time, need for reoperation, time to return of bowel function, length of hospital stay, and readmission. They also found that laparoscopy was associated with a significantly lower rate of wound infection.[110] They concluded that while laparoscopy may have lower rates of wound infection, the similarity in surgical outcomes between laparoscopy and open procedures does not show an advantage to either approach.

The advancement of laparoscopic techniques for the management of Crohn’s disease has been augmented by the use of alternative methods, including robotic-assisted laparoscopy, HALS, and SILS. Robotic-assisted laparoscopic surgery has gained significant attention in the treatment of colorectal disease. A meta-analysis of 39 studies including 13 ileocecal resections, 220 right colectomies, 190 left and sigmoid resections, 440 anterior resections, 149 abdominoperineal resections, and 11 total or subtotal colectomies, demonstrated acceptable rates of conversion and morbidity.[111] Recently, a study of 17 robot-assisted proctectomies and ileal pouch-anal anastomosis procedures in patients with Crohn’s colitis demonstrated similar rates of operative blood loss, postoperative complications, and impact on bowel and sexual function, compared to their laparoscopic counterparts.[112] While the evidence in the colorectal literature is growing, the use of robotic-assisted laparoscopy remains experimental and should only be used by experienced robotic surgeons in selected patients at the present time.

CONCLUSION

Crohn’s disease is a complicated disease that affects the entire gastrointestinal tract and significantly impacts the health and quality of life of patients who suffer from it. Medical management has greatly improved the treatment options and outcomes of patients, and remains an active frontier of research. However, despite improvements in medical therapy, the majority of Crohn’s disease patients still require surgical intervention in their lifetimes.

Although surgery cannot cure Crohn's disease, it continues to play a significant role in managing what can be life-threatening complications and improving disease symptomatology and patient quality of life. As discussed in this chapter, the management of Crohn's colitis is complicated, and therefore treating surgeons must remain abreast of the relevant literature, comprehensive in their knowledge of the disease, and current in surgical technique. Minimization of morbidity, preservation of gastrointestinal function, and improvement in quality of life are all of priority when caring for patients with Crohn's disease.

Chapter 369

COMPLICATIONS OF SURGERY

ABSTRACT

The majority of patients with Crohn's disease eventually require surgery within ten years of diagnosis, most often due to failure of medical therapy or obstruction secondary to ileocolic stenosis. Because of the transmural, chronic, inflammatory nature of the disease as well as the inherent characteristics of the Crohn's patient population (young, malnourished, high percentage of smokers, etc.), there are a number of common and often difficult to manage complications associated particularly with surgery for Crohn's disease. These include surgical site infection, intra-abdominal septic complications, anastomotic complications such as stenosis and leak, enterocutaneous fistula, surgical recurrence, and development of venous thromboembolism. Patients with septic complications, penetrating disease, and number of other risk factors such as smoking, weight loss, and steroid use, tend to require multiple reoperations and intestinal resections, putting them at risk for short gut syndrome and ultimately, intestinal failure. One must be able to identify high-risk patients and be aware of the current diagnostic and management principles of Crohn's disease complications in order to prevent progression to these devastating outcomes and minimize morbidity and mortality.

INTRODUCTION

Crohn's disease (CD) is a complex, incurable, chronic condition with significant morbidity. Its natural history includes many complications such as progression to strictures, fistulae, perianal disease, abscesses, and/or colorectal cancer. Almost half of CD patients develop at least one of these complications [1], and the risk is even higher in males and

* Corresponding Author's Email: skavic@smail.umaryand.edu.

smokers [1, 2]. Complications of CD lead to surgery in approximately 80% of patients within ten years of diagnosis [3].

Complications may follow any surgical procedure, and may involve any organ system. For instance, tooth dislodgement may occur with endotracheal intubation, but has little to do with the specific operative procedure. Further, these complications may range from the mild to the life-threatening in severity. Rather than provide an exhaustive list of all potential surgical complications, in this chapter we will attempt to focus on the complications specific to intestinal surgery for CD.

In CD, 40-50% of patients present with disease of the terminal ileum and cecum, while 20-30% present with primarily colonic disease. The most common indications for surgery are failure of medical therapy and/or intestinal obstruction secondary to stricture, but can also include fistula, abscess formation, hemorrhage, cancer, or growth retardation in children. More than half of patients need a second operation or procedure within 20 years after ileocolic resection and anastomosis[4]. The most common surgery for primary disease is ileocecal resection, and the most common surgery for recurrent disease is ileocolic resection. Repeat surgical interventions further increase risk of complications, which accumulate and lead to debilitating disease.

Postoperative surgical complication rates are higher for CD than for other benign diseases and occur in about 5-13% cases [3,5] with a readmission rate of about 3.7% [3]. Rate of medical relapse or recurrence after surgery is even higher – up to 25% in the immediate postoperative period, and up to 100% ultimately. Clearly, early recurrence will further complicate the post-operative course. Given the high degree of morbidity and complexity associated with this disease, it is important to recognize the common complications to which the Crohn's surgical patient is most susceptible and gain a current understanding of their risk factors, diagnosis, and management.

GENERAL RISK FACTORS

Complications usually occur over a short time frame, typically within four years of operation [3]. Short-term complications are infection (surgical site infections and intra-abdominal sepsis), anastomotic complications, bleeding, venous thromboembolus (VTE), and fistula. Many of these –such as anastomotic leak, enterocutaneous fistula, and infection—overlap, and subject the patient to a cycle of readmissions and interventions. VTE and recurrence can occur in the short or long term. Short gut syndrome and intestinal failure are chronic complications of large resections, repeated resections, recurrent complications, and severe, unremitting disease activity. The overall incidences and risk factors reported for each type of complication are summarized in Figure 1.

In general, risk factors for the development of post-operative complications in Crohn's disease and poor outcome are significant pre-operative weight loss (>5 kg or 10% TBW), pre-operative albumin level <3.0 g/dL, prolonged refractory symptoms, young age at diagnosis, primarily small bowel disease, steroid use, presence of two or more co-morbidities, and penetrating disease behavior [6,7,8]. Risk may be reduced by optimization of nutrition [9], use of antibiotics, and percutaneous drainage of abscesses, among other strategies that will be discussed in this chapter.

List of Complications		
	Incidence	Risk Factors
Wound dehiscence	4%	
Surgical Site Infection	9-30%	Steroid use, proximal small bowel disease, smoking, weight loss prior to surgery, obesity
Superficial surgical site infection	9-19%	Poor nutrition, disease type, extended OR time, blood loss during surgery, transfusions, serum CRP level, serum albumin level, serum lymphocyte count
Deep surgical site infection	2%-10%	Crohn's disease diagnosis
Organ Space infection	3-10%	Pre-operative weight loss, extended OR time, open procedures, contaminated dirty wounds
Intra-abdominal Septic Complication	5-30%	Poor nutrition, albumin <3 g/dL, steroids, presence of abscess or fistula at time of surgery, Less common: penetrating disease, extended OR time, hand-sewn anastomosis, articular disease manifestation, disease duration >10 years before surgery, weight loss, thiopurine therapy, colo-colonic anastomosis, recurrent clinical episodes of CD
GI Bleeding	0.5-4.2%	Thickened mesentery, inadequate clearing of the mesentery prior to division, coagulopathy or bleeding dyscrasia
Anastomotic leak	0.5-7%	Steroid use, pre-operative abscess formation, extensive LOA, extended OR time, proximal small bowel disease, low anterior resection, obesity and male gender (extraperitoneal) Less common: ASA class III-IV, emergent surgery, stapled anastomosis
Anastomotic stricture	Up to 50%	Ischemia at anastomosis, anastomotic leak, recurrent disease, inflammation
Enterocutaneous fistula	Up to 33%	Extensive lysis of adhesions, anastomotic leak, recurrent disease, open surgery
Venous thromboembolism	1.4%	Age <40 years, steroid use, anemia, malnutrition, prolonged anesthesia time, complicated IBD, active disease, recent hospitalizations for IBD, smoking
Short gut Syndrome	5-10%	Earlier age at diagnosis, family history of IBD, stricturing disease, younger age at first surgery, surgical complications, aggressive resections, errors in initial diagnosis
Surgical recurrence	3-8 30% at 5 years, 40% at 10 years and 55% at 20 years	Smoking, presence of fistula or intra-abdominal sepsis as the indication for the primary surgery, short duration of disease prior to surgery, perforating disease Less common: steroids, perianal disease, younger age, primarily small bowel disease, primarily large bowel disease, small bowel wall thickening 1 year post-op, structuring disease,

Figure 1. Possible complications of surgery for Crohn's disease, along with incidence and risk factors.

Pre-operative steroid use has been linked to higher risk of postoperative complications [6]. In a large prospective trial of 8000+ patients with Crohn's disease followed over seven years, there was a higher rate of wound dehiscence, need for blood transfusion, infection, VTE, 30-day reoperation rate, and longer hospital length of stay and post-operative length of stay for patients with pre-operative steroid use [10]. Unfortunately, those contemplating

surgery often have some degree of acute illness that is treated with corticosteroids, making their use common in the surgical population.

Immunomodulators [azathioprine, mesalamines, 6-MP, methotrexate, etc] and *biologic agents* such as anti-tumor necrosis factor α (anti-TNF) agents (infliximab, adalimumab, certolizumab pegol) are steroid-sparing and should theoretically reduce the negative effects of steroid use described above. However, anti-TNF agents have inconsistently been linked to risk for post-operative complications [11-14]. A systematic review and meta-analysis of 18 studies found a moderately increased risk of total early complications with infliximab use, particularly infectious complications [13]. Appau found that infliximab was associated with postoperative sepsis but not anastomotic dehiscence [14].

In contrast, another meta-analysis of six studies found no difference in major or minor complication rate, re-operation rate, or 30-day mortality for patients taking infliximab [12]. In a comparative, multicenter trial of 111 CD patients undergoing surgery with anastomosis treated with biologics within two months perioperatively versus 187 control patients, there was no difference in rate or severity of post-operative complications [11]. A small, randomized controlled trial suggested that infliximab was protective for post-operative maintenance therapy compared to other immunomodulators [15,16]. The effect of biologics in addition to that of other immunosuppressive drugs will be further explored as they relate to each complication described below.

INFECTIOUS COMPLICATIONS

Surgical Site Infection

A surgical site infection (SSI) can be superficial or deep incisional or in the organ/space. SSI usually occurs within 30 days of the operation and displays at least one of the following: 1) purulent discharge from the incision or from a drain placed into the organ space; 2) isolation of organisms from the culture of fluid or tissue obtained from the incision or organ/space; 3) the presence of an open wound with signs and symptoms of infection; 4) abscess formation or other evidence of infection on examinations of the incision or organ/space [17]. As one of the most common post-surgical complications, SSI increases medical costs and length of hospital stay.

Colorectal surgery in general predisposes patients to development of SSI due to increased bacterial contamination, creation of ostomies and intestinal anastomoses. This risk is especially pronounced in CD, which is inflammatory in nature and frequently involves an immunosuppressed host at risk for anemia and malnutrition.

According to NSQIP data comparing 35,557 segmental colectomies from 2006-2011, the incidence of post-operative SSI for CD is higher (17-30%) than for other indications, such as diverticulitis (13%) and colon cancer (10%). A diagnosis of CD is an independent risk factor for developing any post-operative infection. CD is an independent predictor of deep incisional SSI and deep organ space SSI, but not superficial incisional SSI. CD patients who develop SSI were more likely to be smokers, have taken steroids, and lost significant weight prior to surgery [18,19].

Compared to colon cancer patients, CD and diverticulitis patients are more likely to have contaminated or dirty wounds (34%). There was no difference in rate of wound dehiscence (1%). CD group had the highest rate of postoperative infectious complications in general—21% - with twice the rate of deep organ space SSI (7%) than for other indications. Laparoscopic procedure lowered the risk of infection. Diabetes was not associated with increased SSI risk [18].

Another large study of 270 patients with CD had a 19% incidence of any septic complication, 10% incidence of wound infection, and 2% incidence of intra-abdominal abscess [20]. Incisional but not organ/space SSI has been correlated with disease type (perforating or fistulizing), length of operation, estimated blood loss during operation, perioperative transfusion, and inclusion of a proctectomy [21, 14]. The type of ileocolic anastomosis (hand-sewn vs. stapled) seems to have no effect on incidence of intra-abdominal abscess or wound infection [22].

There is no current consensus on whether creating a diverting stoma increases or decreases risk of infective complications. Syed found that ostomy creation was associated with increased risk of postoperative wound infection [23]. This may be because most of these ostomies were unplanned and the patients did not undergo proper pre-operative siting. Other studies observed that ostomy creation decreased risk of postoperative infection, potentially due to lack of anastomosis or diversion of stool from a new anastomosis.

There is no difference in incidence of organ space infection after laparoscopic or open ileocelectomy [24,25]. A large retrospective study of 2618 patients evaluated the risk factors for organ space infection after open or laparoscopic ileocectomy and found that increased risk of organ space infection was seen with preoperative weight loss >10% of total body weight, extended operating room time, open procedures, and contaminated or dirty wounds. Rates of stoma creation and steroid use did not affect organ/space infection rate, although they did not know about pre-existing fistulizing or abscessing disease behavior or the use of biologics [19].

Nutritional and inflammatory statuses are also risk factors for postoperative infection. One should perform an adequate preoperative nutrition assessment of the patient prior to CD surgery. Several validated assessment tools exist, such as the Malnutrition Universal Screening Tool (MUST), the Nutritional Risk Scoring 2002 (NRS2002), the Mini- Nutritional Assessment, and Onodera's Prognostic Nutritional Index (OPNI). The OPNI is calculated by taking into account serum albumin and total lymphocyte count, thus also reflecting the patient's inflammatory status, and is inversely correlated with rate of postoperative incisional SSI in CD [21]. Lower OPNI and lower serum albumin are associated with higher SSI risk, as are higher lymphocyte count and CRP level. Additional clinical parameters that can be used to gauge nutritional response are body weight, BMI, and serum albumin. Inflammatory disease activity can also be monitored by measurement of serum haptoglobin, CRP, and white blood cell count.

Potential risk of incurring surgical site complications in patients on other immunomodulating drugs and/or anti-TNF agents should also be discussed pre-operatively. There is significant debate on whether these agents affect postoperative infection risk, with some conflicting information in the literature. Several groups have reported that immunomodulators and/or infliximab are not associated with higher rates of infection, reoperation, or anastomotic leak in patients having surgery for CD [21, 26, 27, 28].

Beyond mere equivalency, it is possible that there is a protective effect at work. The anti-inflammatory nature of infliximab may actually reduce incisional SSI, especially in fistulizing disease. One multi-institutional study of 217 patients found that combined steroids and anti-TNF α therapy did increase risk of postoperative intra-abdominal infection while anti-TNF α alone did not [29].

Other studies, including a recent systematic review, did find an increased postoperative infection risk with anti-TNF agents [13, 14, 23, 30], and these studies recommended avoiding surgery within 8-12 weeks of initiating anti-TNF therapy in patients at higher risk for postoperative infectious and surgical site complications, if possible. At present, it may be prudent to maintain biologic therapy, and not routinely change the timing of biologic agents administered to those undergoing surgery, but to minimize infusion within one month of operation.

Additionally, higher doses of infliximab in CD patients may correlate with postoperative infection risk, overall postoperative morbidity, and hospital readmissions [31]. It is important to keep in mind, however, that the patients on anti-TNF agents in these studies are more likely to display aggressive disease behavior, be treated with immunomodulators, and have other risk factors such as anemia, malnutrition, fistulae, and past surgeries. Overall, the trend is towards continuing use of pre-operative infliximab in patients with penetrating or fistulizing disease, and maintaining close observation of the wound in these patients since they may be at higher risk.

INTRA-ABDOMINAL SEPTIC COMPLICATIONS

Intra-abdominal septic complications (IASC) encompass anastomotic leaks, intra-abdominal abscesses, or enterocutaneous fistula (ECF). The incidence of post-operative intra-abdominal septic complications exceeds that for other benign diseases, and is estimated to occur between 5-30% [6, 32, 33, 34]. IASC prolong hospital stay, affect quality of life, and increase the risk of surgical recurrence [6]. Even more importantly, IASC accounts for about half of postoperative deaths in CD [33]. Therefore, it is critical to identify both pre- and post-operative clinical risk factors in order to understand how to prevent and optimally manage IASC in CD.

Several studies have examined risk factors for IASC. The *independent risk factors* that have been most consistently identified are listed in Figure 2, and represent a combination of patient disease and treatment factors. These factors are poor nutritional status or low albumin level <3.0 g/dL [11, 23, 33, 35] steroid use [32, 33, 34] presence of abscess, and presence of fistula at time of surgery [11, 32, 33, 34]. According to Yamamoto, the risk of post-operative IASC was 50% if all four of these risk factors were present and 29% if three of four were present [33]. To confound this relationship, it is unclear whether steroid-related infectious complications are a result of its immunosuppressive side effects, or simply reflective of the severity of disease activity.

Other *less commonly reported risk factors* for IASC are: recurrent clinical episodes of CD [32], penetrating disease, operation time >180 minutes [34, 35], hand-sewn anastomosis [35], articular disease manifestation, duration of symptoms before surgery, disease duration of more than 10 years, weight loss, thiopurine therapy [11], colo-colonic anastomoses [11, 34].

Figure 2. Independent risk factors for postoperative intra-abdominal septic complications.

Some researchers have found that the number, site or method of anastomoses does not affect septic complications [33]. In general, surgical teaching has been that affected bowel only needs to be resected to grossly normal margins, assessed intraoperatively by visual means alone. However, one study found that positive histological margins in patients undergoing ileocolic resection are a risk factor for postoperative IASC. Thus, some have suggested that if an anastomosis is constructed in a patient at high risk for infection, one might send frozen sections of the margins to assist the decision to make a temporary diverting ileostomy.

Penetrating or perforating disease (i.e., presents with abscess, fistula, or free perforation with peritonitis) has been identified by several studies as an independent risk factor for postoperative IASC, surgical recurrence, and overall complication rate. Compared to patients with non-perforating indications for ileocolic resection (i.e., fibrostenotic), patients with perforating disease have longer, more complex operations, are less likely to be performed laparoscopically, and more likely to require preoperative TPN, an ileostomy, and a longer postoperative stay [36]. These patients should be managed with thorough preoperative evaluation including optimization of nutrition and cessation of smoking, combined with percutaneous drainage and antibiotics when appropriate.

ABSCESSSES

Abdominal and/or pelvic abscess develop as complications of the disease itself. In surgical patients, abscess develops post-operatively after Crohn's surgery in up to 9% of patients in ten years [37], especially in those with anastomotic leaks or postoperative fistulae. Those with penetrating or perforating disease behavior are more likely to develop abscess than those with stricturing or inflammatory disease [36]. Most abscesses develop near the anastomotic site [37], and almost all require intervention. However, abscesses can develop in almost any location, and have been reported in the abdominal wall, peritoneal cavity, retroperitoneum, iliopsoas, and subphrenic region [37].

There are three conceptual approaches to treating an abscess: medical management with antibiotics; percutaneous drainage; or surgical drainage, with or without resection of involved segments. About 25% of abscesses will recur after treatment [37], although this rate is lower with surgical drainage than with those treated medically or via percutaneous drainage.

Medical management and percutaneous drainage can be used to delay or prevent re-operation if better suited for the patient's clinical condition. Regardless of approach, earlier intervention to drain abdominal or pelvic abscesses is associated with shorter time to resolution [38].

There is no difference between anastomotic technique (stapled or hand-sewn) on the incidence of postoperative abscess [22]. Interestingly, patients who present with abscesses are less likely to undergo laparoscopic surgery [36], although it is not a contraindication to laparoscopic surgery. Ideally, pyogenic complications should be managed electively and after nutritional repletion to prevent long-term complications [39]. Of course, this is not always possible in the setting of acute illness or sepsis.

STRATEGIES FOR PERIOPERATIVE INFECTION CONTROL

Presence of intra-abdominal abscess at time of laparotomy increases risk of postoperative IASC by five-fold [32]. Accordingly, percutaneous abscess drainage should be utilized before definitive surgery, and has been shown to significantly reduce the occurrence of severe postoperative IASC in CD as well as hospital length of stay [40]. Percutaneous drainage allows time for medical optimization with parenteral hyperalimentation, bowel rest, and antibiotics before surgery, as well as reduces pus contamination at time of surgery to enable anastomosis and avoid stoma. Timing of surgery after percutaneous drainage is variable, with most surgeons recommending a 4-6 week interval to allow for resolution.

As with any elective procedure, the patient should be medically optimized prior to planned surgery. This includes correction of anemia, fluid deficits, electrolyte and acid-base disorders, and malnutrition. Preoperative TPN for at least 18 days is recommended for patients with moderate to severe CD to minimize risk of early postoperative complications [9]. For those who can tolerate it, exclusively enteral nutrition may be appropriate, as one study found it reduces the risk of postoperative intra-abdominal septic complications after operation for ECFs in CD [41].

Preoperative imaging with CT enterography or MR enterography may assist in adequate planning and identification of extraluminal complications. In theory, this identification before operation should reduce operative duration and infectious risk. However, CT imaging should be ordered with discretion in CD patients, since they may require repeated scans over time and accumulate radiation risks [42]. Mechanical or chemical bowel preparations are not required to safely perform intestinal surgery in CD patients. Intravenous second-generation cephalosporin or ciprofloxacin plus metronidazole for prophylaxis should be given 30 minutes before surgery and every 3 hours during the procedure.

ANASTOMOTIC COMPLICATIONS

The most common anastomotic complications are bleeding, dehiscence and leaks, strictures, and fistulas.

Bleeding can be minor or major and is thought to occur due to inadequate clearance of the mesentery prior to division and/or stapling of the bowel. There may be an increased tendency to bleed due to the inherent friability of the blood vessels, coupled with the inflammatory

process that surrounds the vessels in a thick, fatty coat. Minor bleeding from the staple or suture line manifests as passage of blood or dark stool with the patient's first bowel movement. This bleeding is self-limited and resolves within 24 hours.

Major bleeding occurs in 0.5-4.2% of patients undergoing anastomosis following all cause colorectal surgery [43, 44]. In the colorectal literature, there is no difference in incidence of postoperative bleeding between benign versus malignant indications. Further, the technique of anastomosis (stapled vs. hand-sewn) does not have an effect on the incidence of bleeding [44].

Management of post-operative bleeding in CD patients follows the same principles of managing lower gastrointestinal bleed in any surgical patient. Specifically, the initial measures are aimed at preserving intravascular volume by administering resuscitative intravenous fluids, blood transfusions, and correction of any underlying coagulopathy. Surgery, angiography, and/or endoscopy are reserved for those who are unstable or have failed conservative management. Early endoscopy, however, may carry a risk for anastomotic dehiscence and disruption of friable tissue, thus should be performed with great care. Persistent bleeding from a low anastomosis may be assessed transanally with a proctoscope and managed with suture ligation. Higher anastomoses need endoscopy, angiography, or re-operation. Angiography is particularly important to identify and possibly treat the bleeding source either without surgery or before surgery. Intraoperative enteroscopy can also be used, but may be difficult to perform in the presence of many strictures.

Major bleeding can also occur intraoperatively if the patient has a very thickened, friable mesentery. The associated diseased bowel loop must be handled and resected with extreme caution, as tearing the friable mesentery can result in profuse and rapid bleeding. It is advisable that patients with thickened mesenteries on pre-operative evaluation undergo open laparotomy in case the surgeon needs to control hemorrhage quickly. In the event of mesenteric tearing or difficult-to-perform vascular control of a thick mesentery, the surgeon should obtain proximal control of the root of the mesentery with large, non-crushing non-traumatizing clamps to minimize further blood loss. Upon release of the clamp, bleeding areas can be controlled with hemostats, suture ligatures, or an energy device [45]. In general, the mesenteric division should occur with clamps and ties rather than relying on energy devices, which may not have the same efficacy in the thickened mesentery of CD.

ANASTOMOTIC LEAK

Anastomotic leak is perhaps the most feared surgical complication of CD surgery, as it can lead to difficult-to-treat enterocutaneous fistulae and/or intestinal failure. Anastomotic leaks are associated with prolonged hospital stay and increased risk of in-hospital mortality.

Like other surgery of the lower GI tract, the risk of anastomotic leak seems to increase with an increasingly distal location of the anastomosis. The reported leak rate for an ileocolic anastomosis is 0.5-7.0% with a mortality rate of up to 20%. Ileocolic anastomoses are different from other colonic anastomoses with regard to bacterial characteristics, bowel caliber, wall structure, location in abdomen, staple technique, and anastomotic leak rate [46]. However, coloanal anastomoses tend to have a higher leak rate (10-20%) [47].

Risk factors for anastomotic leak depend on whether the anastomosis is extraperitoneal or intraperitoneal. Low anterior resection with an extraperitoneal anastomosis is not the most common surgery in CD, but it does carry the highest anastomotic dehiscence rate (8%). The risk is inversely correlated with distance of anastomosis from the anal verge and blood flow to the anastomotic site. Obesity and male gender are also risk factors for extraperitoneal anastomoses due to the more difficult dissection encountered in the deep pelvis.

Intraperitoneal anastomoses—such as jejunoileal, ileoileal, and ileocolic—are at higher risk for leak in patients with significant comorbidity (ASA class III to V), prolonged operative time, extensive lysis of adhesions [11], proximal small bowel disease [11], steroid use, presence of pre-operative abscess, and perhaps, emergent surgery. In one series, the risk of anastomotic complications and overall infectious complications doubles in patients with either steroid use or pre-operative abscess, and is nearly 40% if both risk factors were present [48].

Corticosteroids impair anastomotic healing through a number of mechanisms: they decrease activation and infiltration of inflammatory cells (macrophages and neutrophils) that are critical in the first phase of wound healing; and they inhibit growth factors, matrix proteins, and collagen synthesis. There is no consistent evidence describing dose or duration of steroids that cause anastomotic complications. Arbitrarily, one study defined steroid use as 10 mg or more of prednisone or equivalent for at least 4 weeks and within 2 weeks of surgery [48]. Most clinical experience suggests that steroid doses exceeding 20mg a day confer a significant additional risk.

The incidence of postoperative leak is not affected by laparoscopic versus open surgical approach (2.6% vs. 2.1%) [49]. However, there is substantial variability in technique that makes interpreting the literature difficult. Many surgeons that offer a laparoscopic technique will perform the anastomosis extra-corporeally, via the extraction incision. Others perform the surgery completely laparoscopically. The use of specific energy devices, stapling technology, anastomotic arrangement, and the level of training all serve to leave the practitioner scanning the literature with the sense that there are as many techniques as there are authors.

The data is truly inconclusive as to which anastomotic technique is best for CD surgery. In a meta-analysis of six randomized controlled trials and 955 patients undergoing ileocolic anastomosis for both benign and malignant disease, hand-sewn anastomoses were associated with a significantly higher leak (6% vs. 1.4%) in cancer patients, but there was no difference between hand-sewn and stapled on the incidence of anastomotic leak for non-malignant disease [22]. Besides being faster to perform and requiring less handling of the bowel, stapled anastomosis may lead to less spillage and a more uniform closure, potentially explaining why fewer anastomotic leaks were seen in the overall group of patients included in the meta-analysis [22]. There does not appear to be a benefit for stapled over hand-sewn anastomosis for leak rate after colorectal anastomosis, and it may actually lead to higher chance of stenosis in colon anastomoses.

Again, for CD patients specifically, there is significant variation in the literature on this topic. Representative of this discussion is one Italian study from 2005, where a 7 fold reduction in anastomotic complications was observed when stapled techniques were used instead of hand-sewn anastomoses [50]. On the other hand, another group clearly demonstrated intestinal complications and early reoperation were significantly reduced by use

of a hand-sewn anastomosis [51]. At present, many surgeons prefer the convenience of stapled anastomoses, and the most common configuration is side-to-side.

To avoid complication, one should keep in mind the following standard requirements of an intestinal anastomosis: maintenance of adequate blood flow, freedom from tension, and presence of minimal to no contamination and infectious disease in the abdomen. The decision to avoid anastomosis and resort to an ostomy in CD surgery should also take into account degree of malnutrition, dose of steroids, and severity of co-existing septic issues. Other strategies that have been explored to reduce leak rate are application of fibrin glue and mechanical bowel preparation, although no randomized controlled trials support these tactics as of yet.

Anastomotic leaks usually manifest clinically between postoperative days five and seven, although up to 12 percent occur after postoperative day 30 [52]. Leaks are diagnosed by the presence of fecal discharge from the drain or wound, development of postoperative enterocutaneous fistula originating from the anastomotic site, or evidence of peritonitis on physical exam. Most patients present with signs of sepsis or peritonitis, such as pain, fever, and tachycardia.

In the unstable patient with generalized peritonitis or high-grade sepsis, emergent exploratory laparotomy should be undertaken immediately. If a stable patient shows signs of a clinical leak and low-grade sepsis, management begins with timely initiation of supportive care: fluid resuscitation and broad spectrum antibiotics. If the patient is hemodynamically stable, a CT scan with oral, intravenous, and rectal contrast or a water-soluble enema is obtained. The findings of fluid collections or gas containing collections on CT scan are highly suggestive of anastomotic leak. Imaging is used to determine location of leak, severity, and whether fluid collections are in continuity with the leak.

A subclinical leak is apparent radiographically, but the patient may be asymptomatic, and this can be managed with observation. A free intraperitoneal leak should be taken to the operating room for exploration and repair. If the patient is stable and there are small (<3 cm), contained abscesses on imaging, the patient can be treated conservatively with bowel rest and broad spectrum antibiotics. Larger abscesses (>3 cm) should be drained percutaneously if feasible, with surgery reserved for abscesses not amenable to drainage or if patient's clinical condition does not improve. Intraoperatively, if the primary finding is an inoperable phlegmon, drains can be placed by the anastomosis and a proximal loop ileostomy or colostomy created for temporary fecal diversion. A small anastomotic defect may be repaired primarily with placement of drains and proximal diversion. An anastomotic defect >1 cm or greater than 1/3 of the circumference can be resected with creation of a stoma, re-anastomosis and proximal diversion, or exteriorization of both ends of the stoma. Recurrence rate is lower in those whose anastomosis is taken down and end-ileostomy created [6].

STRICTURE

Anastomotic strictures are another common and unfortunate complication of CD surgery. Colorectal strictures are defined as the inability to pass a scope at least 12 mm in diameter through the stenosis. Clinically, the patient may be asymptomatic or present with partial or complete bowel obstruction. Recurrent disease at the site of anastomosis eventually causes

transmural inflammatory edema and fibrosis, leading to stricture in about half of patients three years after ileocolic resection. Stricture at the site of ileocolic or colorectal anastomosis may also result from tissue ischemia, anastomotic leak, and inflammation. Recurrent strictures lead to re-operation and further resections, potentially leading to short gut syndrome. Sites of inflammation may be identified at operation, and even marked with a metal clip to aid in future radiographic identification.

If presenting with obstruction, strictures in CD should first be treated conservatively with intravenous hydration, nasogastric suction, and parenteral nutrition if necessary. Surgery and is no longer the only intervention available to open the stricture. Ileocolic, colocolic, or higher colorectal strictures may be managed with endoluminal therapy, in addition to stricturoplasty, or conservative resection and anastomosis. Lower colorectal anastomoses can also be dilated digitally or with serial dilators.

Endoluminal therapy may delay the need for surgery or avoid it altogether. In a meta-analysis of 13 studies and 347 patients, endoscopic balloon dilation was feasible in 86% of cases and had minimal complications [53]. It is effective for short strictures (<4 cm), but relapse rate is high, requiring repeat dilation in up to 50% of patients. Limited case series and datasets describe the utility of self-expandable metal stents to treat anastomotic and other intestinal stenoses in CD patients, but there are several complications (migration, restenosis, perforation, and fistulization) that can occur. Some argue that stents should not be placed into sites of active inflammation and should be used primarily as a short-term bridge to definitive management. The durability and efficacy of endoluminal stents has not yet been adequately studied.

FISTULA

Most fistulae associated with CD are internal and spontaneous as a result of transmural inflammatory disease activity. These fistulae can form between any two loops of bowel or between bowel and adjacent structure, such as bladder, ureter, or vagina. Fistulizing Crohn's is best treated medically with infliximab, azathioprine, or 6-MP, but sometimes surgical resection is required. This section will not focus on these spontaneous fistulae, but rather, will discuss enterocutaneous fistula (ECF) as a result of intestinal surgery for CD.

In fact, about 20% of all ECF are related to CD. Following colorectal surgery, the most common causes of enterocutaneous fistula are anastomotic leak and failure to recognize an inadvertent enterotomy. CD is an especially potent risk factor (4.68 times higher than other causes) for development of early postoperative enterocutaneous fistula, which is associated with 2.5 fold higher in-hospital mortality compared to patients without early postoperative ECF [54]. As expected, lysis of adhesions is associated with higher postoperative ECF rate, and laparoscopic surgery is associated with a lower rate of ECF; however, these associations were described for all-cause colorectal surgery and not specifically for CD [54].

Postoperative ECF clinically present as a patient who fails to do well immediately after surgery. A protracted clinical course may include development of fever, prolonged ileus, malaise, and/or abdominal distension and tenderness. On postoperative day 5-10, a wound infection may appear followed by drainage of enteric contents from the wound [55].

Management of ECFs in this setting is complex, multidisciplinary, and depends on surgeon experience and judgment. Along with initial resuscitation and treatment of any associated sepsis with antibiotics, the drainage should be contained to minimize skin irritation and further wound contamination. It is important to identify the fistula either clinically or radiologically with CT scan or fistulogram to determine where it occurs and whether it arises spontaneously from healthy bowel after a resection, from diseased bowel, or from an anastomotic breakdown. If arisen from healthier bowel, it has a high likelihood of spontaneous closure, and can be treated non-operatively with bowel rest and parenteral nutrition. Patients with ECF from diseased bowel may benefit from early resection due to lower likelihood of spontaneous closure and higher tendency to re-open. If an abdominal wall abscess is present, it should be drained immediately to resolve the local sepsis.

Though not always possible, the ideal timing of surgical repair of a spontaneous ECF is best when inflammation has subsided as much as possible and the abdominal wall has become soft [45]. Timing of repair of an early post-operative ECF is more controversial. Some studies found that re-operation within 9-10 days avoids a higher mortality associated with operating at a later time [55]. However, some surgeons advocate conservative management, if possible, since the patient is still in an inflammatory, immunosuppressed, and potentially undernourished state, making it likely that another fistula will form. Reoperation can be attempted in 4 or 5 months, if the patient is cooperative and the clinical condition is otherwise stable.

Common principles of fistulae repair apply: 1) transection of the fistulous tract; 2) resection of the diseased segment; and 3) primary closure of the fistulous opening on the target organ [56]. If the ECF is chronic and the surrounding tissue is inflamed, the incision can be made away from the fistulous tract. This will not only simplify dissection, but also reduce the chance of postoperative wound healing problems.

Laparoscopic surgery for fistulous complications is feasible and safe [57]. In twenty patients with CD and fistulae treated with surgery, hospital length of stay was eight days and oral intake resumed on postoperative day one. Other studies have echoed that laparoscopic surgery is safe and feasible, although, of course, with proper training [58].

Fluid, electrolyte, and nutritional support are key factors in the management of post-operative ECF. Intravascular volume is usually depleted due to third spacing from bowel distension and/or fistula output, and the patient must be resuscitated to normal levels in a timely fashion. Patients with ECF tend to have deficiencies in sodium, phosphate, potassium, and magnesium. These electrolytes should be monitored closely and repleted. Poor perioperative nutrition has been linked to poor surgical outcome including higher mortality in several studies. Total parenteral nutrition is indicated to meet the metabolic demand, and it is associated with both disease remission and higher spontaneous ECF closure rates. If the patient has sufficient small bowel for absorption (typically greater than 100 cm), a combination of parenteral and enteral feeds is desirable. Enteral feeds may increase fistula output and should be given with great caution to avoid hyperosmolar concentrations and intestinal necrosis.

Recently, exclusive enteral nutrition (EEN) has been proposed as a strategy to induce remission and combat surgical complications. EEN modifies intestinal microbiota and has purported anti-inflammatory and pro-mucosal healing effects [59]. Li showed retrospectively that EEN for at least three months before operation for ECF reduced the risk of anastomotic complications after bowel resections [41]. These patients achieved an albumin level of <

4g/dL and lower CRP (thus lower inflammatory activity) at time of operation than the non-EEN patients.

COMPLICATION RATES AFTER SPECIFIC TYPES OF SURGICAL PROCEDURES

Depending on the location and severity of the disease, colonic CD can be treated by either segmental resection, subtotal colectomy with ileorectal anastomosis, or total proctocolectomy. The complications for each of these surgical approaches have been compared. A meta-analysis comparing outcomes for segmental resection vs. subtotal/total colectomy with ileorectal anastomosis in six different studies (488 patients, 265 segmental resection vs. 223 ileorectal anastomosis) found no significant difference in the incidence of surgical recurrence between the two types of operations, but the segmental resection group recurred 4.43 years earlier than the ileorectal anastomosis group. There was no difference in incidence of other postoperative complications. [60] Recent reviews advocate use of segmental colectomy whenever possible, as the 5 year recurrence-free survival, need for stoma, and quality of life were not significantly different compared to subtotal colectomy [61]. The likelihood of requiring stoma depends on presence of current or past perianal sepsis at time of resection and presence of more than one co-morbidity [61].

In another study of CD patients with primary colonic disease, there was an earlier recurrence interval for those treated with segmental resection than those treated with total proctocolectomy. Patients with distal colonic involvement were more likely to require a permanent stoma than those with isolated proximal colonic involvement. [62].

LAPAROSCOPIC AND OPEN TECHNIQUES

Recent meta-analyses of non-randomized trials report that laparoscopic ileocolic resection leads to reduced perioperative complications, incisional hernia, length of stay, and postoperative ileus compared with open surgery. However, in a meta-analysis of two randomized trials, there was no significant difference in incidence of wound infections, pneumonia, length of stay, postoperative narcotic use, reoperation rates of CD recurrence, or reoperation for non-CD related complications between patients in the open and laparoscopic groups [63]. The data for laparoscopic colectomy are similar, showing no effect on the complication rate. Taken together, these data suggest that laparoscopic surgery for CD is feasible, safe, and associated with good outcomes [64, 65, 66] but does not show a clear advantage over open surgery based on the relatively few and small randomized controlled trials we have so far.

In experienced hands, laparoscopy can be performed safely even for complicated CD [64, 67]. In one series of a single surgeon, despite increasing complexity of cases, there was a significant decrease in hospital length of stay after laparoscopic ileal resection with time [67]. Another group found no difference in minor or major complications of laparoscopic colorectal surgery during the learning curve, and the mean operative time did not decrease over time [8].

Conversion from laparoscopic to open surgery is associated with higher rates of both minor and major complications [8]. Common reasons for conversion include encountering complex masses, dense adhesions, abscesses, fistulae, or other complications of previous resections [67]. The complication rate for elective laparoscopic surgery for CD in one series was 8.7% for minor and 5.4% for major complications [8]. This particular study originally reviewed complications for all indications for colorectal surgery, and observed that overall, low anterior resection and male gender were risk factors for conversion. Low rectal pathology is generally considered a risk factor for high-grade complications such as intra-operative bleeding, ureteral injury, and anastomosis-related complications, most likely due to the extensive pelvic dissection in these cases.

Another prospective study reported a conversion rate of 30% in CD patients undergoing ileocolic resection, and identified two independent risk factors for conversion: recurrent medical acute episodes of CD and unexpected intraperitoneal abscess or fistula [68]. Age is not considered a risk factor for complications after laparoscopic surgery; in fact, laparoscopic approach for colorectal resections is generally considered lower risk than open surgery in older patients [69]. Together, these data suggest that patients who present with low rectal pathology, especially male patients, should be approached with an open or modified hybrid approach (such as laparoscopic vessel ligation, splenic flexure mobilization, and open pelvic dissection through a lower midline incision), and one should maintain a low threshold for conversion in a patients with both recurrent flares of CD and finding of intraabdominal sepsis at initial laparoscopy.

To reduce risk of conversion, decrease operative time, and enable tactile feedback as a tool to assess diseased bowel, the hand-assisted laparoscopic surgery (HALS) is a viable alternative to laparoscopic or laparoscopic-assisted surgery. HALS has been reported to be safe and feasible in complex Crohn's colitis with no increase in postoperative complications [70].

Single-port laparoscopic surgery (SILS) is another available minimally invasive approach. So far, limited data exists on SILS in the Crohn's population. One study reviewed single-port ileocectomy for terminal ileum stenosis reported it as safe and feasible, with similar rates of conversion (1/20) and overall complication rate (20%) as the laparoscopic-assisted controls in that study [71]. The single-port approach did not decrease post-operative pain scores or hospital duration. Again, those that practice SILS recommend thorough familiarity with the laparoscopic approach before adopting SILS [72].

RECURRENCE

Recurrence after resection is another common complication in CD patients. Indeed, without proper medical therapy, all patients with CD can be expected to experience disease recurrence ultimately. Recurrent disease carries significant economic burden and is an independent predictor of lower patient quality of life scores, regardless of surgical approach and cosmesis outcome [61].

Recurrence can be discovered during endoscopic follow-up (histologic or endoscopic recurrence). When symptomatic, recurrence can be clinical (requiring medical intervention)

or surgical (requiring re-operation). The usual location for disease recurrence is the anastomosis region, and is surprisingly common.

Endoscopic recurrence is evident in 70-90% of patients at one year after surgery [73] and manifests as aphthous and serpiginous ulceration. Endoscopic recurrence correlates with the likelihood of needing future intervention, thus it is important to perform endoscopic follow-up evaluation 6-12 months after surgery [74] to identify those patients at risk for recurrence. It is not yet clear whether severity of endoscopic recurrence correlates with clinical severity.

The risk of recurrent clinical disease after a primary operation for Crohn's disease is approximately 17-55% at 5 years, 32-76% at 10 years, and 72-73% at 20 years [2, 4, 75]. The risk of surgical disease increases over time as well, occurring in up to 30% at 5 years, 40% at 10 years and 55% at 20 years [76]. Recurrent operations are associated with higher complication rates than primary procedures (17% versus 6.52%).

Several risk factors for recurrence have been examined. Cigarette smoking is consistently associated with all levels of recurrent disease, increasing the risk by two-fold. Additionally, quitting smoking reduces post-operative recurrence [4]. Education and encouragement are crucial in the management of these patients. Recent studies have noted that perforating disease, presence of fistula and/or post-operative intra-abdominal sepsis at time of primary surgery are risks for early recurrence [6].

A 2005 review of all studies describing risk factors for recurrence concluded that the following do NOT consistently increase recurrence, though may have been cited as risk factors in individual studies: age at onset of disease, sex, family history of Crohn's disease, anatomical site of disease, length of resected bowel, presence of granuloma in the specimen, blood transfusions, and post-operative complications [4]. Short duration of disease prior to first operation was a risk for recurrence, but it is not recommended to delay surgery simply based on this prognosticator. Risk of recurrence was higher in patients with small bowel disease in some studies, especially proximal (duodenal or upper jejunoileal) disease, but other studies found that recurrence was higher for predominantly large bowel disease; therefore, "anatomical site" is not a reliable parameter for prognosis. Presence of perianal disease is an independent risk factor for recurrence [76, 77].

In one prospective trial, the authors also saw more recurrence in patients who presented with younger age, small bowel wall thickening 12 months after surgery, and stricturing disease behavior [5]. Typically, perforating disease has been linked to higher rates of and earlier recurrences (1.7 years versus 13 years) and overall worse prognosis, thus the data for differing recurrence rates based on disease type is also inconclusive.

Although intuitively it would seem that recurrence rate may be lower in CD colitis patients who undergo total colectomy and ileostomy rather than ileal resection with anastomosis, there are several recent studies that suggest that surgical approach does not affect recurrence rate. This applies to laparoscopic versus open surgery, as well as radical versus non-radical resection. Thus, limited resection techniques such as stricturoplasty and segmental resection are still justified.

Anastomosis configuration may also affect recurrence rate, although there is conflicting data for this modifiable risk factor as well, as previously discussed. Most retrospective studies found that stapled functional end-to-end anastomosis is the method of choice to reduce recurrence and complications [4]. In another series, hand-sewn side-to-side anastomoses led to lower recurrence rates in the long term than stapled end-to-end or end-to-side [51].

PROPHYLAXIS

The high rate of recurrence after CD surgery has spurred significant research in the area of prophylactic therapy. The mechanisms of action and drug profiles of the various medical therapies available are beyond the scope of this chapter, but we will briefly discuss the current literature regarding their efficacy in preventing surgical recurrence. A target of prophylactic therapy is observation of mucosal healing (MH), or the absence of ulcers on endoscopic visualization. Mucosal healing has been associated with fewer complications and recurrences after surgery [78].

Prophylactic corticosteroid therapy does not seem to reduce recurrence rate [4]. A number of earlier randomized controlled trials and a 2009 Cochrane systematic review suggest that nitroimidazole antibiotics (metronidazole, ornidazole), 5-ASA (mesalamine), 6-mercaptopurine, and azathioprine are all effective in reducing post-operative clinical and endoscopic recurrence. Efficacy of sulfasalazine is not yet clear. Utility of these agents should take into consideration their risk of adverse events, which was higher with nitroimidazoles (metallic taste, GI upset, or neuropathy) and azathioprine/6-MP than with mesalamine [79]. The authors recommend considering these agents in the first 3 months after surgery in high-risk patients. Combination therapy with AZA and metronidazole in this short-term period enhances the benefit of AZA by approximately 20%. Azathioprine and 6-MP, in particular, may be more effective at maintaining remission in patients who have undergone intestinal resection (not colectomy) for CD complications and are left with minimally involved areas not yet requiring resection but rather ongoing immunosuppressive therapy.

Chemoprevention with biologics has been gaining momentum, as anti-TNF agents have shown success in reducing long-term recurrence. In a small, randomized placebo-controlled study of 24 adult patients, administration of infliximab after intestinal resection (at 0, 2, and 6 weeks, then every 8 weeks for 54 weeks) successfully prevented endoscopic, histological, and clinical recurrence of CD at one year follow-up (9.1% recurrence vs. 84.6% in placebo group) [80] without an increase in adverse events. In this study, the infliximab treatment group had a significantly higher number of smokers. This suggests that patients who are at high risk for post-operative recurrence of CD (such as smokers, or those with post-operative sepsis, ileal penetrating disease, or recurrent resections) should be considered for postoperative infliximab prophylaxis.

The role of enteric microflora in the pathophysiology of inflammatory bowel disease is another topic of recent interest, since recurrence seems to occur more in bowel exposed to enteric contents compared with bypassed intestinal segments. Probiotics such as *Lactobacillus johnsonii*, *Lactobacillus rhamnosus*, or cocktails of several probiotics have shown promising results in the prevention of pouchitis; however, meta-analysis of the few randomized controlled trials available show no significant difference in their effect on clinical recurrence [79].

Poor nutrition may also contribute to recurrence. Preoperative parenteral and enteric nutrition have both shown to reduce postoperative complications, potentially then reducing risk of repeat operations [9, 41]. Postoperative long-term elemental enteral nutrition (low fat diet supplemented with nocturnal elemental nasogastric feeds) prevented endoscopic and clinical recurrence in a small non-randomized trial, although patient compliance was an obstacle in maintaining the nutritional regimen [81].

In summary, strategies that may reduce risk of recurrence in high risk CD patients include: smoking cessation, control of intra-abdominal sepsis prior to operation, possibly anastomosis configuration, use of prophylactic antibiotics and immunomodulating or biologic agents, and nutritional supplementation. Clinical parameters that may identify patients at risk are: younger age (<30) at presentation, duration of disease, disease behavior, repeat resection, and proximal disease. Endoscopic follow-up within the first year of operation should be performed. Active disease should prompt intensification of immunosuppression.

SHORT GUT SYNDROME AND INTESTINAL FAILURE

Though less frequent than in earlier eras, short gut syndrome (SGS) after bowel resection is still a relatively common and debilitating complication of recurrent surgery for Crohn's disease. SGS can occur after a single large resection or as a result of repeated resections. SGS leads to intestinal failure if the remaining small intestine lacks the surface area and capacity to digest and absorb nutrients. SGS is usually defined as <200 cm of small intestine remaining, and signs of malabsorption usually present at <110-130 cm or <70-90 cm of small bowel with intact colon. Very short gut syndrome has been defined as <50 cm of small intestine and associated malabsorption.

Risk factors for SGS include early age at CD diagnosis (before age 16), family history of CD, early age at first surgery, penetrating disease, aggressive resections, surgical complications, and errors in initial diagnosis [82, 83, 84]. In a retrospective review of 82 patients with intestinal failure, the median duration of CD before intestinal failure was 26 years, median time from disease onset to diagnosis of intestinal failure was 18 years, and patients had a median of five intestinal resections. 47% had SGS due to primary active CD requiring resections, and 29% had SGS due to operative complications, such as leaks, fistulas, or ischemia as a result of surgery; 24% had both.

Symptoms of SGS are dehydration, diarrhea, weight loss, and nutritional deficiencies. Clinical severity and approach to therapy depend on SGS type (three types) based on the level of the intestinal anastomosis: Type I) end-jejunostomy; II) jejunocolic anastomosis; and III) jejunoleileal anastomosis. Depending on the type of SGS, adaptation of the remaining bowel occurs over time, which involves intestinal lengthening and dilation, growth of villi, deepening of crypts, hyperplasia of enterocytes, and enlargement of folds, in order to enhance surface area for absorption [85].

Intestinal adaptation is poorest in Type I, in which there is chronic, severe fluid and electrolyte losses. Type II has a slower intestinal transit than Type 1, higher degree of adaptation, and preservation of colon that aids in fiber digestion and fatty acid absorption. Type II clinically presents with chronic under-nutrition. Type III rarely presents with malnutrition, as these patients are more able to tolerate enteral feeds. Loss of ileum is the most perilous, as the jejunum is less able to adapt, and there is loss of the ileal brake mechanism, which appropriately slows intestinal transit to maximize reabsorption. Additionally, loss of the ileocecal valve allows colonic flora to colonize the small bowel, increasing risk of small intestinal bacterial overgrowth and its associated symptoms and malabsorption.

Prevention of SGS is a priority for the IBD surgeon. In patients requiring repeat operations, bowel-sparing techniques and minimally invasive resection should be used whenever possible. While one retrospective study claimed that positive margins predicted post-operative intraabdominal septic complications, a randomized controlled trial showed that absence or presence of negative margins does not have an effect on recurrence rate [86]. Therefore, resection should be limited to the most diseased portions to avoid development of short gut syndrome. In addition, the surgeon should liberally consider use of stricturoplasty in CD.

Management of short gut syndrome is complex and may require consultation with a nutrition specialist. Fluid and electrolyte replacement is essential with care taken to avoid hypotonic hypo-osmolar liquids, hyperosmolar liquids, or liquids with diuretic effects such as alcohol and caffeine. Small frequent meals with high caloric intake comprised mostly of carbohydrates and protein is an ideal dietary plan. Most patients are also on some regimen of antidiarrheal/antimotility medication, antisecretory medication, and/or growth factors. If patients continue to fail medical management, they may be considered for intestinal transplantation.

VENOUS THROMBOEMBOLISM

Venous thromboembolism (VTE) including deep venous thrombosis (DVT) and pulmonary embolus (PE) are known complications in patients with inflammatory bowel disease. For both CD and ulcerative colitis (UC), the annual risk for VTE is 0.26%-0.3% [87], increased by two-fold over the general population [88]. The risk is higher in hospitalized IBD patients versus non-hospitalized, and about 2/3 of VTE cases occur in patients who have had an intestinal resection.

Compared to non-IBD patients, IBD patients are at higher risk for postoperative VTE (1.4% for CD and 3.3% for UC) [89] within 30 days of colorectal surgery. The thromboembolic episodes tend to occur around 10 days postoperatively. The overall risk of VTE is equal for UC and CD patients, but higher in hospitalized UC patients compared to hospitalized CD patients. Patients under 40 years of age are at the greatest risk, which is earlier in life than occurrence of VTE in non-IBD patients.

Risk factors for postoperative VTE in IBD patients are steroid use, anemia, malnutrition, and prolonged anesthesia time [89], as well as complicated CD (fistula, stenosis, abscess), active disease, and recent hospitalizations for CD for overall VTE risk. Traditional risk factors such as smoking may also play a role. VTE recurs in 10-13%. It is associated with higher morbidity (longer length of stay, more in-hospital complications) and mortality (4% vs. 0.9%) [89].

A meta-analysis of 33 studies showed that in addition to DVT and PE, CD patients also had a higher risk of ischemic heart disease and mesenteric ischemia, although these were not necessarily post-operative occurrences and there was no increased risk of cardiovascular mortality. [88]. Tight control of inflammation with immunosuppressives and biologic agents may help reduce risk of thrombovascular disease in CD patients, but currently there are no studies that measure impact of CD medications on this particular complication.

In a retrospective review of IBD patients with VTE, 50% of the patients who developed VTE during the hospital stay were not receiving pharmaceutical DVT prophylaxis. Despite clinical practice guidelines recommending that hospitalized IBD patients receive dual prevention with mechanical and pharmaceutical prophylaxis given that there are no contraindications to unfractionated or low molecular weight heparin, up to 35% of physicians do not follow these guidelines [90], perhaps due to a perceived risk of bleeding. There is no consensus for a standardized agent or approach to anticoagulation tailored to type of IBD (Crohn's or UC), severity, surgical procedure, or length of hospitalization.

OTHER COMPLICATIONS

Other rare complications of Crohn's disease surgery are small intestine adenocarcinoma or colorectal cancer, free intestinal perforation (2.4%), enteroenteric intussusception, and urinary tract infection (UTI). Free perforation has been reported in about 100 cases and should be managed with resection and anastomosis instead of simple suture repair. Enteroenteric intussusception presents as upper abdominal distension in patients who have had ileocecal resection. It is thought to be most likely due to dilated ileal segments from prior obstructions. Differential diagnosis includes small bowel obstruction or stricturing disease. In the few case reports that describe this complication, no Crohn's disease segments were found in the resected areas [91]. CD was found to be an independent predictor of UTI in one broad series for patients who had undergone segmental colectomy and may be related to prolonged hospital stay [18].

GRADING SYSTEMS

Grading post-operative complications serves as a useful comparative tool for quality control and predicting surgical risk in patients for whom surgical consequences would dramatically affect quality of life. There are several grading systems that have been shown to be useful in predicting 30-day morbidity and mortality, although there is not yet an IBD-specific grading system available. The POSSUM score (Physiological and Operative Severity Score for the enUmeration of Mortality and Morbidity) is one such validated tool that has been found to be precise in predicting 30-day morbidity in patients with abdominal Crohn's disease [92].

Mazeh prospectively validated a grading system that introduced a severity scale of 1-5 for complications of colorectal surgery in 2114 patients. They found that complication grade correlated with length of stay and identified a number of factors that predicted postoperative complications [93]. Asa validated the use of a grading system for complications associated with elective laparoscopic colorectal surgery in 501 patients and found that conversion to open was associated with both minor and major postoperative complications. Complication grade was again directly related to length of stay. In this study, CD was the indication for surgery in 5.6%, cancer in 56.5%, polyps in 20%, diverticular disease in 9.2%, and "other" for 9% [8].

CONCLUSION

The main complications of surgery for Crohn's disease are related to the inherent inflammatory nature of the disease and clinical features of the patient population. They include an increased rate of wound infections, intra-abdominal abscesses, anastomotic complications, enterocutaneous fistulae and venous thromboembolic events than the general surgical population. Complications are even higher in patients who smoke tobacco, are diagnosed or operated on earlier in life, have penetrating disease behavior, malnutrition and weight loss, chronic steroid use, and/or intra-abdominal sepsis at the time of operation. Complications lead to re-operation in about half of patients. Patients with multiple resections are at risk for short gut syndrome. Strategies to reduce post-operative complications are cessation of smoking, optimization of preoperative nutrition, preoperative antibiotics and percutaneous drainage of abscesses, limited resection techniques, routine endoscopic follow-up, use of standard postoperative VTE prophylaxis, and judicious use of steroid-sparing immunomodulating and biologic agents.

Chapter 370

ASSESSMENT OF OVARIAN RESERVE BEFORE AND AFTER GYNECOLOGIC SURGERY

Akira Iwase*

Department of Maternal and Perinatal Medicine,
Nagoya University Hospital, Japan

ABSTRACT

Anti-Müllerian hormone (AMH) serum levels have been recently applied to the assessment of ovarian reserve apart from infertility treatments due to the advantages in clinical use, such as intra- and inter-cycle consistency. Surgical interventions for benign gynecologic conditions as well as diseases themselves possibly affect ovarian reserve. Such gynecologic conditions and interventions include endometriosis/endometriomas, benign ovarian tumor, hydrosalpinx, ovarian cystectomy, salpingectomy, and hysterectomy. Most studies demonstrate a decline in serum AMH levels after cystectomy for endometriomas, especially in bilateral cases. It is not conclusive whether electrocoagulation or suturing as a surgical method for hemostasis after cystectomy is preferable for ovarian reserve. The effects of other gynecologic diseases including benign ovarian cysts/tumors and interventions, such as hysterectomy and salpingectomy, on ovarian reserve are controversial. Ovarian reserve is severely decreased following unilateral oophorectomy with/without chemotherapy, in patients with ovarian malignancies who desire future fertility. Serum AMH levels allow quantitative evaluation of ovarian reserve, and should be considered as a marker in determining the indication and selection of operative methods for benign gynecologic conditions. However, there is little available information regarding the correlation between the probabilities of live births and serum AMH levels before and after surgical interventions.

INTRODUCTION

Benign gynecologic diseases are often implicated in fertility problems, and therefore, interventions are required to improve fertility in such conditions. Gynecologic diseases without any concomitant fertility problems, such as endometriosis with severe dysmenorrhea, are indications for fertility-preserving interventions in women who desire future fertility. However, surgical interventions involving the uterus, fallopian tubes and ovaries, have been demonstrated to potentially affect ovarian function, as these interventions might decrease ovarian cortical tissues and blood supply to ovaries [1-3]. In some cases, benign gynecologic diseases themselves may affect ovarian function and ovarian reserve. Therefore, interventions for benign gynecologic conditions aiming to preserve fertility as well as benign gynecologic diseases themselves prior to interventions must be assessed from the point of view of ovarian reserve.

Malignant gynecologic conditions are different from benign ones in fertility preservation. Preserving fertility following treatment for malignant ovarian tumors is particularly challenging. With proper and careful selection of patients, more conservative surgery to preserve the uterus or ovaries may be feasible in patients with early-stage epithelial ovarian cancers, low malignant potential ovarian tumors, or malignant germ cell ovarian tumors [4-6]. However, in these patients, maintaining ovarian function following treatment can be a serious issue if unilateral oophorectomy, possibly followed by chemotherapy, is performed.

The clinical utility of measuring serum anti-Müllerian hormone (AMH) levels has been evaluated in a wide range of health-care issues in women. Apart from infertility treatments, in the last decade, other possible clinical uses for ovarian reserve tests have been explored [7, 8]. Such uses include assessment of ovarian damage caused by chemotherapy, radiation, and surgery, as a marker of ovarian insufficiency, and possible predictive marker for menopause [9]. For these purposes, AMH has some advantages in clinical use, such as its sensitivity for decline with advancing age and intra-cycle consistency, which can make blood tests possible independent of the menstrual cycle [10].

This chapter focuses on the assessment of ovarian reserve after gynecologic interventions. Also included is an assessment of the influence of gynecologic diseases, such as endometriosis and endometriomas, on ovarian reserve and discuss what mechanisms are associated with the disturbance of ovarian reserve prior to surgical interventions. Other ovarian toxic interventions, such as chemotherapy and radiotherapy, are not included in this chapter. In addition, there will be particular reference to post-surgical ovarian reserve in women with fertility-preserving surgery for malignant ovarian tumors.

OVARY

Surgical interventions involving the ovaries can potentially cause damage to ovarian function because of the loss of ovarian cortex and/or detrimental effects on blood supply to the ovaries [11]. Post-surgical changes, such as inflammation, might affect ovarian follicle pool and therefore, be involved in the post-surgical decrease in ovarian reserve. Surgical procedures include cystectomy for endometriomas and other ovarian tumors, which are often performed as part of infertility treatments. Therefore, a decline in ovarian reserve after these

interventions must be kept to a minimum. Serum AMH levels allow for the quantitative evaluation of ovarian reserve. Assessments of a surgical procedure's influence on ovarian reserve using serum AMH levels as a marker may be helpful for improving these surgical indications and interventions.

On the contrary, ovarian cysts/tumors themselves might affect ovarian reserve. Thinning and fibrosis of the ovarian cortex is a potential mechanism involved in the decrease in ovarian reserve in affected ovaries. Hence, the indication, timing, and modalities of surgical interventions must be evaluated, and compared from the standpoint of the influence of ovarian cysts/tumors themselves and the surgical procedure on ovarian reserve.

Endometrioma and Endometriosis

Excision of the endometrioma capsule is superior to drainage and electrocoagulation of the endometrioma wall to increase spontaneous pregnancy rates in infertile women with ovarian endometrioma undergoing surgery [12]. On the other hand, there is no evidence that cystectomy for endometriomas prior to treatment with assisted reproductive technologies improves pregnancy rates [12-14]. Taken together, the significance of ovarian reserve after surgery for endometriomas is dependent on post-surgical infertility treatment. Serum AMH levels prior to surgery also should be assessed from this standpoint.

The ovarian cortex surrounding endometriomas has been reported to potentially cause a reduction in the volume of healthy tissue, to lower follicular density, and cause a loss of cortex-specific stroma [15-17]. These results suggest that endometriomas might result in diminished ovarian reserve. Lemos et al. reported that infertile patients with minimal/mild endometriosis without endometriomas, categorized as stage I/II according to the revised American Society for Reproductive Medicine (rASRM) classification [18], have decreased serum AMH levels compared to those in a control group with tubal obstruction without endometriosis [19]. With regards to endometriomas, Kim et al. demonstrated that patients with stage IV endometriosis with endometriomas displayed significantly lower AMH levels than age- and body mass index (BMI)-matched controls [20]. Similarly, it has been reported that AMH levels are lower in patients with stage III/IV endometriosis without prior ovarian surgery than in controls [21]. Uncu et al. also reported lower AMH levels in patients with endometrioma than in age-matched controls [22]. In this study, the unilateral endometrioma group exhibited lower AMH levels than the bilateral endometrioma group. However, a cross-sectional study including 313 women with a diagnosis of endometriosis and 413 women without endometriosis (controls) identified no difference in serum AMH levels correlated to the type of endometriosis excluding women who had a past history of surgery for endometriomas [23].

It is still inconclusive whether and how endometriosis and endometriomas affect serum AMH levels, although several studies have reported decreased levels of serum AMH in endometriosis patients (Table 1). Inflammation surrounding ovaries might have some influence on ovarian reserve, if serum AMH levels are altered by endometriosis without endometriomas. Moreover, endometriosis and endometriomas might affect not only the quantitative aspects of ovarian reserve, but also the quality of oocytes.

Table 1. Serum anti-Müllerian hormone (AMH) levels in endometriosis and endometrioma surgery

Author (Year)	Ref	Comparison	Serum AMH level (ng/mL)	P
Control vs. Endometriosis

Surgery for Endometrioma

Busacca et al. reported 3 cases of post-surgical ovarian failure in a total of 126 patients who underwent bilateral endometriomas [24]. Surgeons should keep ovarian reserve in mind particularly when considering surgical intervention for bilateral endometriomas.

Unlike the controversy regarding the influence of an endometrioma itself on ovarian reserve, warnings that cystectomy for endometriomas diminishes ovarian reserve has been supported by data regarding the number of oocytes retrieved in *in vitro* fertilization (IVF) procedures [11]. Chang et al. and Iwase et al. first reported that cystectomy for endometriomas leads to a greater decrease in serum AMH levels than cystectomy compared to other benign ovarian tumors [25, 26]. Among the subsequently published pioneer studies, one study demonstrated that cystectomy for endometriomas did not cause significant changes in serum AMH levels (Table 1) [27-32]. These studies have already been reviewed and a meta-analysis has led to the conclusion that cystectomy for endometriomas may cause a decline of ovarian reserve [33, 34]. A cross-sectional study also demonstrated that AMH levels were significantly lower in women who previously underwent endometrioma surgery, irrespective of whether endometriomas were present at the time of the study ($P < 0.05$) [23].

Factors Affecting Ovarian Reserve in Endometrioma Surgery

Several issues have emerged regarding surgery for endometrioma and ovarian reserve. The first issue concerns the factors causing post-surgical decreases in ovarian reserve. One such factor is bilateral surgery. It has been reported that laparoscopic cystectomy for bilateral endometriomas caused a greater decline of serum AMH levels compared to unilateral cystectomy [25, 26]. Hirokawa et al. reported a greater rate of decline in serum AMH levels 1 month after surgery for bilateral endometriomas compared with unilateral tumors ($24.7 \pm 32.5\%$ in the unilateral surgery vs. $62.8 \pm 29.6\%$ in the bilateral surgery, mean $\pm$ SD of the decline rates; $P < 0.001$) [29]. The Authors also found that higher rASRM scores tended to cause greater reduction in serum AMH levels after surgery. Kitajima et al. compared the decline of serum AMH levels within 3 months after surgery in women with an excised cyst wall that contained normal ovarian tissue and women without healthy ovarian tissue in the excised cyst wall ($42.0 \pm 32.9\%$ vs. $8.9 \pm 13.4\%$; $P = 0.01$) [30]. Recently, a study of 193 patients who underwent laparoscopic cystectomy for endometrioma demonstrated that postoperative AMH levels significantly decreased after surgery irrespective of age (≤ 38 years, $P < 0.001$; > 38 years, $P < 0.001$), cyst size (> 3 cm, $P = 0.018$; ≤ 3 cm, $P = 0.022$), and laterality (unilateral, $P < 0.001$; bilateral, $P < 0.001$) [35].

The second issue concerns the determination of which surgical methods are optimal from the standpoint of postoperative AMH levels (Table 1). Although excision of the endometrioma capsule is superior to drainage and electrocoagulation of the endometrioma wall in spontaneous pregnancy rates [12], most gynecologists believe that cauterization and vaporization of the cyst wall is ovarian reserve-friendly. The “three-step technique,” consisting of irrigation during the first laparoscopy, followed by treatment with a gonadotropin-releasing hormone agonist, and vaporization in the second laparoscopy, resulted in a lower post-surgical decline in AMH levels compared to endometrioma stripping [32]. Bipolar electrocoagulation may potentially damage the cortex of ovaries. Several studies have

compared different hemostasis methods in ovarian cystectomy for endometriomas. Ferrero et al. compared serum AMH levels following hemostasis by bipolar coagulation versus suturing after laparoscopic cystectomy for bilateral endometriomas [36]. They found no significant difference in the mean percentage decrease in AMH levels in the two groups after 3, 6, and 12 months of follow-up. Another randomized controlled trial (RCT) compared the effects of hemostatic matrix with bipolar electrocoagulation in unilateral cystectomy for endometrioma [37]. Serum AMH levels in the bipolar coagulation group were significantly lower at 1 month after surgery and were similar at 3 months after surgery compared to AMH levels in the hemostatic matrix group. Zaitoun et al. prospectively compared laparoscopic cystectomy with bipolar coagulation and laparotomic cystectomy with sutures. Only the laparoscopic cystectomy group displayed a significant decrease in AMH levels [38].

The third issue to be addressed is the recovery of serum AMH levels after surgery for endometriomas. AMH is produced by primary, preantral, small antral follicles but not by primordial follicles [39]. If rearrangements of follicle cohorts from a healthy primordial follicle pool occur, then serum AMH levels that decrease because of surgery could be expected to recover. Two early studies indicated that serum AMH levels could be restored to some extent by 1 week, 1 month, and 3 months after cystectomy for endometriomas [25, 31]. In the aforementioned RCT, AMH levels, especially in the bipolar coagulation group, tended to recover at 3 months after surgery compared with 1 month after surgery [37]. On the contrary, several studies have demonstrated that serum AMH levels gradually decreased or remained low [22, 36, 40, 41]. Celik et al. assessed serum AMH levels preoperatively and at 6 weeks and 6 months after surgery and reported that AMH levels gradually decreased in patients with bilateral tumors or in those with cyst diameters ≥ 5 cm [40]. Sugita et al. reported that serum AMH levels could be higher or lower 12 months after surgery compared to those observed 1 month after surgery [42]. They indicated and speculated that the immediate postsurgical decline of serum AMH levels was possibly related to the reduction of cortex volume from the excision, and that the medium/long-term decrease might be caused by other factors, including reduced blood supply to the ovaries.

Benign Ovarian Cysts

Matsuzaki et al. demonstrated that the surgically excised cyst wall contained a detectable number of follicles found in normal ovarian tissue following endometrioma surgery, while the cyst wall of other benign ovarian tumors did not contain any accidentally removed ovarian cortex [43]. Therefore, from the standpoint of the influence of cystectomy on ovarian reserve, one must distinguish benign ovarian cysts/tumors from endometriomas.

No significant difference was observed in preoperative serum AMH levels between the mature cystic teratoma group and age- and BMI-matched controls (Table 2) [20]. Iwase et al. reported that laparoscopic cystectomy for non-endometriomas (15 cases of unilateral tumors and 5 cases of bilateral tumors) caused a lesser, but significant, decline in AMH levels (Table 2) [26]. Similarly, Chang et al. reported that serum AMH levels were lower 1 week after laparoscopic cystectomy for non-endometriotic cysts (69.2% of the preoperative AMH levels; $P < 0.05$) [25]. Jang et al. recently reconfirmed the results from Iwase and Chang [44]. The decline in serum AMH levels after cystectomy for benign ovarian tumors have been reported to be lower than those after cystectomy for endometriomas. Chang et al. reported that the

decline in serum AMH levels at 1 week after laparoscopic cystectomy was smaller for non-endometriotic cysts than for endometrioma (69.2% vs. 33.9% of preoperative AMH levels; $P = 0.028$) [25]. A similar tendency was reported by Iwase et al. with a degree of decline of AMH levels compared to preoperative levels of 16.1% in the benign ovarian tumor group vs. 24.9% in the endometrioma group [26].

Table 2. Serum anti-Müllerian hormone (AMH) levels in benign gynecologic conditions except for endometriosis

Author (Year)	Ref	Comparison	Serum AMH level (ng/mL)	P

^a mean $\pm$ SD; ^b mean $\pm$ SEM; ^c median; ^d mean; ^e originally reported in pmol/L; MCT, mature cystic teratoma; NS, not significant.

To date, only one prospective randomized study has compared serum AMH levels after cystectomy for unilateral non-endometriotic cysts using laparoscopy and laparotomy [45]. Significant differences have been found in AMH levels between the laparoscopy and laparotomy groups at 1, 3, and 6 cycles after cystectomy (Table 2).

Ovarian Malignancies

Iwase et al. compared postoperative levels of AMH in women with ovarian malignancies and AMH levels post-cystectomy for benign ovarian tumors as a control to assess the impact of the fertility-preserving surgery with or without chemotherapy on ovarian reserve. They found that the mean AMH level in the treatment group measured 0.9 ng/mL, which was significantly lower than the levels measured in the control group (4.70 ± 3.77 ng/mL, mean $\pm$ SD) [46].

FALLOPIAN TUBE

A hydrosalpinx can reduce the likelihood of pregnancy after IVF. Therefore, salpingectomy of diseased fallopian tubes before IVF should be considered [47]. Salpingectomy might result in decreased blood supply to the ovaries. However, the ovarian response after salpingectomy has been inconsistent [48, 49]. Of course, it is not clear whether the hydrosalpinx itself may affect ovarian reserve. Only one cross-sectional study has assessed serum AMH levels in different tubal surgical procedures. No significant differences were found in serum AMH levels among patients undergoing different tubal surgical procedures, including 26, 34, 23, and 51 patients who underwent bilateral salpingectomy, unilateral salpingectomy, bilateral interruption in the proximal oviducts, and bilateral oviduct obstruction, respectively [50]. On the contrary, Grynnerup et al. reported that AMH levels were significantly lower in the salpingectomy group than in the non-salpingectomy group (Table 2) [51]. Sequential assessments of serum AMH levels did not reveal statistically significant differences before and after laparoscopic coagulation and dissection of the proximal tubes (1.548 ng/mL preoperatively vs. 1.481 ng/mL 3 months after surgery, median; $P = 0.079$) [52]. Similarly, a study also illustrated that serum AMH levels were not affected by tubal ligation (1.43 ng/mL preoperatively vs. 1.30 ng/mL 12 months after surgery, median; $P = 0.23$) [53].

UTERUS

Hysterectomy

Hysterectomy is not an option in women who desire future fertility. However, ovarian sex steroid hormones are necessary for relatively younger women even after hysterectomy. Therefore, simultaneous oophorectomy in hysterectomy for benign uterine diseases should be avoided in women aged less than 45 years. Hysterectomy, even if the ovaries are preserved, can possibly cause adverse effects on ovarian function. Subsequently, it might shorten the time to menopause [54, 55]. Serum AMH levels showed tendency to decline more at 4 months after hysterectomy compared to those in controls who did not undergo hysterectomy, although this was not statistically significant (Table 2) [56]. The authors concluded that the decrease in ovarian reserve after hysterectomy is possibly caused by low blood supply because of the interruption of the uterine arteries. On the contrary, Lee et al. revealed that

hysterectomy did not affect ovarian artery blood flow or serum AMH levels (Table 2) [57]. However, Wang et al. demonstrated that serum AMH levels significantly declined 3 months following hysterectomy, whereas AMH levels 3 months after myomectomy were similar to the preoperative levels (Table 2) [58].

Simple hysterectomy for benign diseases is performed with or without salpingectomy. The mesosalpinx plays a role in blood supply to ovaries. Therefore, prophylactic salpingectomy with hysterectomy should be reconsidered. Salpingectomy with total laparoscopic hysterectomy (TLH) did not cause a significant decrease in AMH levels compared to those observed after standard TLH without adnexectomy (-0.06 ± 0.1 ng/mL vs. -0.08 ± 0.1 ng/mL Δ AMH for TLH with vs. without salpingectomy, mean $\pm$ SD; $P = 0.35$; where Δ AMH refers to the change in post-operative and pre-operative values of AMH) [59]. This result was confirmed in an RCT by Findley et al. (Table 2) [60].

Myomectomy

Leiomyoma of the uterus is one of the most frequently observed benign gynecologic conditions affecting fertility. Abdominal or laparoscopic myomectomy is performed for leiomyoma patients who desire future fertility. A small, but statistically significant, decrease in postoperative serum AMH levels was found in the myomectomy group [26]. On the contrary, Wang et al. demonstrated that serum AMH levels 3 months after myomectomy were similar to the preoperative levels [58]. Myomectomy is a procedure in which severe hemorrhage can occur. Therefore, a decrease in blood supply during surgery might affect ovarian reserve. However, serum AMH levels greatly differed in the above two studies, and therefore, it would be difficult to draw a definitive interpretation.

CONCLUSION

It can be concluded that the current status of pre- and post-gynecologic surgery as follows: 1) the influence on ovarian reserve with endometriosis/endometrioma itself is still controversial and this influence might not reach clinical significance as far as serum AMH levels are concerned; 2) cystectomy for endometriomas tends to reduce AMH levels more than cystectomy for other types of benign ovarian tumors, especially in bilateral endometriomas; 3) cystectomy and bipolar coagulation in endometrioma surgery could be factors that decrease ovarian reserve; however, no definitive conclusions can be made about which surgical method is preferable from the standpoint of ovarian reserve; and 4) although hysterectomy, salpingectomy, and myomectomy might affect ovarian reserve, conclusions remain speculative since evidence is insufficient. Tables 1 and 2 show the representative results available to date regarding serum AMH levels and gynecologic conditions and surgeries.

This chapter focused on the clinical utility of AMH levels as a marker for the evaluation of ovarian damage caused by gynecologic diseases and surgery. A meta-analysis using two randomized studies has shown that stripping was superior to vaporization or coagulation of the cyst wall in terms of rates of spontaneous pregnancy and disease recurrences [61-63].

However, vaporization or coagulation has been demonstrated to be more favorable in terms of ovarian reserve [11]. Most studies have evaluated ovarian reserve in terms of the numbers of oocytes retrieved in IVF procedures. However, all women who underwent surgery for endometriosis did not necessarily require IVF treatment. Not surprisingly, the increasingly widespread use of AMH measurement has boosted research to identify the most appropriate indication and surgical methods for treatment of endometriomas. As mentioned above, several studies have revealed that cystectomy for endometriomas causes a decrease in ovarian reserve especially in bilateral cases. The loss of ovarian cortex removed accidentally and/or by electrocoagulation for hemostasis is the primary reason for a decrease in ovarian reserve. A small number of studies show that suturing or using hemostatic materials without bipolar electrocoagulation might be preferable in the preservation of ovarian reserve. Disturbance of the blood supply has been considered another cause affecting ovarian reserve in endometrioma cystectomy. Adhesiolysis is one of the main components of endometriosis surgery. Anatomical corrections including excessive adhesiolysis might cause the diminished blood supply to the mesosalpinx. Surgical methods for endometriomas including cystectomy or vaporization/coagulation, suture or electrocoagulation as a hemostasis method, should be reevaluated from the standpoint of ovarian reserve. However, further studies, including rates of pregnancy and recurrences after surgery, are required in order to evaluate the true usability of serum AMH levels as a marker in endometrioma surgery.

In addition to endometrioma surgery, surgical interventions for other gynecologic conditions that might cause ovarian damage should be evaluated in terms of ovarian reserve. It is controversial whether cystectomy for benign ovarian tumors, with the exception of endometriomas, negatively affects ovarian reserve. The decline in ovarian reserve possibly caused by salpingectomy, which is occasionally performed for ectopic pregnancy or hydrosalpinx, is also an issue that should be addressed. There is a possibility that other surgical procedures for removal of fallopian tubes besides salpingectomy, such as dissection of the tubes may be preferred, although the available evidence is too limited to draw a conclusion. Sex steroid hormones secreted by the ovary, such as estrogen, are important for women's healthcare even if patients do not foresee a future pregnancy. Therefore, when considering ovarian life after hysterectomy, the assessment for ovarian reserve using AMH has an important role. The studies performed so far have not reported a huge influence, although the impacts on ovarian reserve by such interventions are not conclusive.

Ovarian reserve is severely reduced following unilateral oophorectomy with/without chemotherapy, in patients with ovarian malignancies. Assessment of ovarian reserve using serum AMH levels as a marker of ovarian reserve would be valuable for fertility planning in patients with ovarian malignancies.

In conclusion, measurement of serum AMH levels is helpful for counseling patients who desire future fertility but have benign and malignant gynecologic conditions that may require surgical interventions. Serum AMH levels may be preferred in helping to determine the indication and selection of surgical methods for benign gynecologic conditions, especially endometriomas. However, there is little available information regarding the correlation between the possibility of eventual live births and serum AMH levels pre- and post-operative procedures. Further studies are required to investigate whether and to what degree serum AMH levels in patients with gynecologic conditions, including fertility-preserving interventions for ovarian malignancies, are relevant to prospective live births.

QUESTIONS FOR FURTHER RESEARCH

What surgical procedure including hemostatic method for endometriomas is the most appropriate to maintain ovarian reserve?

Can pre- and post-surgical AMH levels in gynecologic diseases predict future live births?

Is ovarian reserve affected by non-ovarian gynecological diseases, such as uterine leiomyomas and hydrosalpinx, and its surgical procedures?

Chapter 371

FOLLOW-UP AFTER TREATMENT OF LOCALIZED RENAL TUMOR (SURGERY, SURVEILLANCE, ABLATIVE THERAPIES)

Francisco Javier Perez Garcia*, PhD

Department of Urology, Hospital San Agustin, Aviles, Asturias, Spain

ABSTRACT

Renal cell carcinoma (RCC) comprises approximately 2%-3% of all adult malignancies, representing the seventh most common cancer in men and nine commonest cancers in women. Surgical resection (radical or partial nephrectomy) remains the only effective therapy for clinically localized RCC. Other treatment options like Active Surveillance and Ablation therapies can be used in selected patients.

Follow-up after surgery, active surveillance and ablation treatment allows the urologist to monitor for postoperative complications, renal function, local recurrence, recurrence in the contralateral kidney and development of metastasis.

A review of the most important and relevant guidelines was conducted to summarize the necessity and the studies to do for surveillance in these patients.

INTRODUCTION

Renal cell carcinoma (RCC) comprises approximately 2%-3% of all adult malignancies, representing the seventh most common cancer in men and nine commonest cancers in women. It is the tenth most common cause of cancer-related deaths among men [1,2]. Risk factors for RCC include active and passive smoking, obesity, end-stage renal failure, acquired renal cystic disease and hereditary conditions associated with a mutation in the von-Hippel-Lindau gene [3,4]. Surgical resection (radical or partial nephrectomy) remains the only effective therapy for clinically localized RCC. Other treatment options like Active Surveillance and Ablation therapies can be used in selected patients.

* Corresponding Author's Email: franjapg@yahoo.es.

Surgical management with resection of the primary tumor provides for immediate local control of renal tumors and valuable pathologic data that may aid in understanding prognosis and guide patient follow-up.

Indications for active surveillance include elderly patients, those with decreased life expectancy or those with medical comorbidities that would be associated with increased risk if a therapeutic intervention were to be undertaken. Alternatively, a strategy of observation with delayed intervention as indicated may be elected in order to determine the growth rate or to obtain alternative diagnostic imaging. Ablative techniques may be performed by a variety of approaches (open/laparoscopic/percutaneous) and operators (urologic surgeons/interventional radiologists). The majority of neoplasms selected for ablative procedures are less than 4 cm and exophytic, as markedly higher incomplete ablation rates have been noted for endophytic, central and larger neoplasms.

Staging

The Union for International Cancer Control tumour–node–metastasis staging system should be used (Table 1).

Risk Assessment

RCC is recognised as having a very variable natural history. Risk assessment models have been developed to provide prognostic information for patients and to inform the eligibility and risk stratification designs of clinical trials. [5]

**Table 1. The Union for International Cancer Control
tumour–node–metastasis staging system**

T	Primary tumour
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Tumour of < or = 7cm in greatest dimension limited to the kidney
T1a	Tumour < or = 4 cm
T1b	Tumour > 4 cm but < or = 7 cm
T2	Tumour >7cm in greatest dimension limited to the kidney
T2a	Tumour > 7 cm but < or = 10 cm
T2b	Tumour > 10 cm limited to the kidney
T3	Tumour extends to major veins or perinephric tissues but not into the ipsilateral adrenal gland and not beyond Gerota’s fascia
T3a	Tumour grossly extends into the renal vein or its segmental (muscle-containing) branches, or tumour invades peri-renal or renal sinus fat (peripelvic) but not beyond Gerota’s fascia

T	Primary tumour
T3b	Tumour grossly extends into the vena cava below the diaphragm
T3c	Tumour grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumour invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)
N	Regional lymph nodes
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
M	Distant metastasis
CM0	Clinically no distant metastasis
CM1	Clinically distant metastasis
PM1	Pathologically proven distant metastasis e.g. needle biopsy
Stage Grouping	
Stage I	T1 N0 M0
Stage II	T2 N0 M0 T3 Any N M0
Stage III	T1-3 N1 M0 T4 Any N M0
Stage IV	Any T Any N M1

Localised disease. Two systems can be used to assess the risk of progression in localised tumors: the stage, size grade and necrosis (SSIGN) score [6] and the University of California Los Angeles Integrated Staging System (UISS) [7]. These systems are described in Tables 2 and 3. In SSIGN, risk points are accumulated as noted in Table 2 and added up to provide a risk score.

Table 2. Stage, size grade and necrosis (SSIGN) score for localized RCC

Feature	Score	
Pathological T category of primary tumour (TNM 2002)	pT1a	0
	pT1b	2
	pT2	3
	pT3a-4	4
Regional lymph node status	pNx or pN0	0
	pN1 or pN2	2

Table 2. (Continued)

Feature	Score	
Tumour size (cm)	<10	0
	>10	1
Nuclear grade	1 or 2	0
	3	1
	4	3
Histological tumour necrosis	No	0
	Yes	1
Scores	Group	5-year metastasis free survival (%)
0-2	Low risk	97.1
3-5	Intermediate risk	73.8
> or = 6	High risk	31.2

Table 3. University of California Los Angeles Integrated Staging System (UISS) risk groups and 5-year disease-specific survival

Patient group		Pronostic group			
		T stage	Fuhrman's grade	ECOG status	5-year disease-specific survival (%)
Localised disease (N0, M0)	Low risk	1	1-2	0	91.1
	Intermediate risk	1	1-2	1 or more	80.4
		1	3-4	Any	
		2	Any	Any	
		3	1	Any	
		3	2-4	Any	
	High	3	2-4	1 or more	54.7
		4	Any	Any	
Metastatic disease	Low risk	N1 M0	Any	Any	32
		N2M0/M1	1-2	0	
	Intermediate risk	N2M0/M1	1-2	1 or more	19.5
			3	0, 1 or more	
			4	0	
	High	N2M0/m1	4	1 or more	0

The SSIGN score compared favourably with the UISS score in predictive accuracy in a series of patients who had surgically resected clear-cell RCC. On the other hand, the UISS provides prognostic predictions for both localised and metastatic disease.

Advanced disease. Prognostic models were first built when immunotherapy was the standard therapy. The Memorial Sloane Kettering Cancer Centre (MSKCC) or Motzer score was the standard system. The MSKCC score has now been validated and updated for use in

the current era of targeted therapies as the Heng or International Metastatic RCC Database Consortium (IMDC) criteria [8]. Patients are stratified according to the presence of six risk factors:

- Karnofsky performance status (PS) <80%.
- Haemoglobin <lower limit of normal.
- Time from diagnosis to treatment of <1 year.
- Corrected calcium above the upper limit of normal.
- Platelets greater than the upper limit of normal.
- Neutrophils greater than the upper limit of normal.

The number of risk factors present is added up and the risk is stratified as can be seen in table 4.

Table 4. The Memorial Sloane Kettering Cancer Centre (MSKCC) score

Number of Risk factors	Risk group	Median overall Survival (OS) months	2-year OS (%)
0	Favourable	43	75
1-2	Intermediate	27	53
3-6	Poor	8.8	7

RATIONALE FOR SURVEILLANCE

There is no evidence that any particular follow-up protocol influences the outcome in early RCC. No standard recommendation can be given for the follow-up in advanced RCC either. The follow-up scheme for localized RCC following surgery should be dependent on the therapeutic possibilities upon recurrence. CT scans of thorax and abdomen are routinely performed, with time intervals dependent on risk factors. Long term follow-up is proposed in some institutions, due to the possibility of late relapse, but its benefit has never been demonstrated. [5]

A review of the most important and relevant guidelines was conducted to summarize the necessity and the studies to do for surveillance in these patients.

According to NCCN guidelines, [9] after surgical excision, 20% to 30% of patients with localized tumors experience relapse. Lung metastasis is the most common site of distant recurrence, occurring in 50% to 60% of patients. The median time to relapse after surgery is 1 to 2 years, with most relapses occurring within 3 years. [10]

When it comes to AUA guidelines, [11] follow-up for adult cancer survivors has traditionally focused on the early detection of a cancer recurrence based on the presumption that treatment of a lower tumor burden would result in better patient outcomes, although the evidentiary data supporting this presumption is limited [12]. The recommended essential elements of adult cancer survivorship care now include not only monitoring for cancer recurrence, secondary cancers and treatment effects, but also the prevention of recurrences or new tumors, medical interventions for the consequences of cancer and its treatment effects

and the coordination between specialists and primary care physicians to meet survivors' needs [13]. Treatment "effects" include those related to the sequelae of surgery, systemic therapies, ablative therapy and radiation.

There is now an increasing rate of detection and subsequent treatment of small renal masses of uncertain biological potential as well as a widening spectrum of contemporary treatment options with varied treatment related effects. Such options include observation/surveillance, ablative therapies and minimally-invasive as well as open approaches to partial and radical nephrectomy. The advent of a new generation of targeted systematic therapy now holds the promise of prolonged survival of patients with metastatic disease. Additionally, patients with renal cell cancer tend to be older and have a greater incidence of pre-existing kidney disease, which places them at an increased risk for either the development or progression of chronic kidney disease following therapy [14-15]. Since effective treatment strategies are available to slow the progression of chronic kidney disease and reduce cardiovascular risks, it would seem prudent to include renal function monitoring in the follow-up of renal cancer patients to facilitate early interventions or referral to nephrology.

Surveillance after surgery allows the urologist to monitor for postoperative complications, renal function, local recurrence, recurrence in the contralateral kidney and development of metastasis. [16]

Renal function and postoperative complications are commonly assessed by history, physical examination, and measurement of serum creatinine and haemoglobin at 4–6 weeks postsurgery. Long-term monitoring of serum creatinine is recommended particularly in patients with compromised renal function prior to surgery or significant increase in creatinine after surgery.

Early diagnosis of local and contralateral kidney recurrence (incidence < 2%) is useful since the most effective treatment is surgical resection. Recurrence in the kidney is associated with positive surgical margins, multifocality and grade. Tumors that develop in the contralateral kidney can be treated with nephron-sparing surgery when detected at a small size. Patients who underwent surgery when local recurrences became symptomatic have a higher rate of incomplete resection of recurrence, positive surgical margins and poorer survival.

Extensive tumor recurrence reduces the possibility of complete surgical resection, which is standard therapy for patients with local recurrence or resectable solitary metastasis.

Furthermore, an early diagnosis of disease relapse may enhance efficacy of systemic therapy if the tumour burden is low. Hence, this supports the rationale for surveillance of patients to detect recurrences and metastases early.

According to the EAU guidelines, there is no consensus on surveillance after treatment for RCC, and there is no evidence that early vs later diagnosis of recurrences improves survival. [17]

It is reasonable to stratify the follow-up, taking into account the risk of a recurrence or metastases developing. There have been large studies examining prognostic factors with long follow-up periods, from which some conclusions can be drawn:

- The sensitivity of chest radiography for small metastases is poor and US has limitations. [18]

- When the risk of relapse is intermediate or high, CT of the chest and abdomen is the investigation of choice. Findings using CT can clearly reveal metastatic lesions from RCC. [19]
- Surveillance should also include clinical evaluation of renal function and cardiovascular risk factors.
- Positron-emission tomography (PET) and PET-CT as well as bone scintigraphy are not the standard of care in RCC surveillance, due to their limited specificity and sensitivity.
- More strict follow-up schedules may be required after cryotherapy and RFA due to the higher local recurrence rate after these modality of treatment.
- There is controversy over the optimal duration of follow-up. Some argue that follow-up with imaging is not cost-effective after 5 years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumors that develop in the contralateral kidney can be treated with nephron-sparing surgery if the tumors are detected when small. In addition, for tumors < 4 cm in size, there is no difference between partial and radical nephrectomy with regard to recurrences during the follow-up. [20]

The American Urological Association published in the year 2013 the guideline for follow-up for clinically localized renal neoplasms and established several guideline statements [11]. Patients undergoing follow-up for treated or observed renal masses should undergo a history and physical examination directed at detecting signs and symptoms of metastatic spread or local recurrence. They should undergo basic laboratory testing to include blood urea nitrogen (BUN)/creatinine, urine analysis (UA) and estimated glomerular filtration rate (eGFR). Other laboratory evaluations, including complete blood count (CBC), lactate dehydrogenase (LDH), liver function tests (LFTs), alkaline phosphatase (ALP) and calcium level, may be used at the discretion of the clinician. Patients with progressive renal insufficiency on follow-up laboratory evaluation should be referred to nephrology.

The guideline recommends a bone scan in patients with an elevated alkaline phosphatase (ALP), clinical symptoms such as bone pain, and/or if radiographic findings are suggestive of a bony neoplasm.

Patients with a history of a renal neoplasm presenting with acute neurological signs or symptoms must undergo prompt neurologic cross-sectional CT or MRI scanning of the head or spine based on localization of symptomatology.

FOLLOW UP AFTER SURGICAL TREATMENT BASED IN NCCN AND AUA RECOMMENDATIONS (TABLE 5)

Low Risk Patients (pT1, N0, Nx)

Patients should undergo a baseline abdominal scan (CT or MRI) for nephron sparing surgery and abdominal imaging (US, CT or MRI) for radical nephrectomy within three to twelve months following renal surgery.

Additional abdominal imaging (US, CT or MRI) may be performed in patients with low risk (pT1, N0, Nx) disease following a radical nephrectomy if the initial postoperative baseline image is negative at the discretion of the clinician.

Abdominal imaging (US, CT, or MRI) may be performed yearly for three years in patients with low risk (pT1, N0, Nx) disease following a partial nephrectomy based on individual risk factors if the initial postoperative scan is negative.

Patients with a history of low risk (pT1, N0, Nx) renal cell carcinoma should undergo yearly chest x-ray (CXR) to assess for pulmonary metastases for three years and only as clinically indicated beyond that time period.

Table 5. Follow up after surgical treatment. Radical or partial nephrectomy

Follow-up Measure	Radical or Partial Nephrectomy	
Physical Exam and History	History and physical examination directed at detecting signs and symptoms of metastatic spread or local recurrence	
Laboratory Testing	– blood urea nitrogen (BUN)/creatinine, urine analysis (UA) and estimated glomerular filtration rate (eGFR). – complete blood count (CBC), lactate dehydrogenase (LDH), liver function tests (LFTs), alkaline phosphatase (ALP) and calcium level, may be used at the discretion of the clinician. – Patients with progressive renal insufficiency on follow-up laboratory evaluation should be referred to nephrology.	
CNS Scan	Acute neurological signs or symptoms must undergo prompt neurologic cross-sectional CT or MRI scanning of the head or spine based on localization of symptomatology	
Bone scan	Elevated alkaline phosphatase (ALP), clinical symptoms such as bone pain, and/or if radiographic findings are suggestive of a bony neoplasm.	
Follow-up Measure	Low Risk	Moderate to High Risk
Abdominal Scan/Imaging	Partial Nephrectomy - Baseline abdominal scan (CT or MRI) within 3 to 12 months following surgery: - If the initial postoperative scan is negative, abdominal imaging (US,CT or MRI) may be performed yearly for 3 years based on individual risk factors Radical Nephrectomy - Patients should undergo abdominal imaging (US,CT,MRI) within 3 to 12 months following renal surgery. - If the initial postoperative imaging is negative , abdominal imaging beyond 12 months may be performed at the discretion of the clinician	– A baseline abdominal scan (CT or MRI) within 3 to 6 months following surgery with continued imaging (US,CT, MRI) every six months for at least three years and annually thereafter to year five – Imaging beyond 5 years may be performed at the discretion of the clinician – Perform site specific imaging as symptoms warrants
Chest Imaging/Scan	Obtain a yearly chest x-ray for 3 years and only as clinical indicated beyond that time period	Obtain a baseline chest scan (CT) within 3 to 6 months following surgery with continued imaging (CXR or CT) every 6 months for at least 3 years and annually thereafter to year five. Imaging beyond 5 years is optional and should be based on individual patient characteristics and tumour risk factors

Moderate to High Risk Patients (pT2-4N0 Nx or Any Stage N+)

Moderate to high risk patients should undergo baseline chest and abdominal scan (CT or MRI) within three to six months following surgery with continued imaging (US, CXR, CT or MRI) every six months for at least three years and annually thereafter to year five.

It is recommended site-specific imaging as warranted by clinical symptoms suggestive of recurrence or metastatic spread.

Imaging (US, CXR, CT or MRI) beyond five years may be performed at the discretion of the clinician for moderate to high risk patients.

Routine FDG-PET scan is not indicated in the follow-up for renal cancer.

**FOLLOW-UP IN ACTIVE SURVEILLANCE
(TABLE 6)**

Indications for active surveillance include elderly patients, those with decreased life expectancy or those with significant medical comorbidities that would be associated with increased risk if a therapeutic intervention were to be undertaken. Alternatively, a strategy of observation with delayed intervention as indicated may be elected in order to determine the growth rate or to obtain alternative diagnostic imaging.

It is assumed that the patient who has been chosen for active surveillance is one who would undergo intervention if, in the course of active surveillance, changes occur in the primary tumor for which intervention would normally be indicated. In the patient for whom no surgical or minimally invasive intervention (i.e., surgery or percutaneous ablative procedure) would ever be considered due to comorbidities, no imaging is necessary.

Follow-up protocols may vary depending on whether the patient has undergone a biopsy of the renal mass. The AUA guidelines considered clinical scenarios including biopsy-proven, untreated, clinically localized renal cancers; biopsies yielding low-malignant potential neoplasms or normal renal parenchyma; and renal lesions radiographically suspicious for neoplasm that either have not been biopsied or have indeterminate biopsy results.

Physicians should counsel patients on their other therapeutic options, as addressed in the AUA Treatment of T1 Renal Mass Guidelines [21]. Specifically, the patient should be counselled about the small but potential risk of cancer progression while on active surveillance, the potential loss of a window of opportunity for nephron-sparing surgery, the lack of curative salvage therapies if metastases develop and the deficiencies of the current data used to support this approach. Potential triggers for intervention while on active surveillance primarily involve absolute tumor size, tumor growth rate or a change in patient preference.

The precise growth rate or absolute tumor size that would trigger intervention is controversial given the limited available data. Some would propose that because the normal growth rate is approximately 0.3 cm/year, a persistent tumor growth rate of greater than 0.3-0.5 cm per year, and/or an absolute tumor size of greater than 3cm would justify intervention. The intervention would primarily involve local treatment, although a biopsy (in the case of biopsy-unproven renal masses) or a change to more frequent imaging could also be incorporated.

Table 6. Follow-up in active surveillance

Follow-up Measure	Active Surveillance
Physical Exam and History	History and physical examination directed at detecting signs and symptoms of metastatic or local progression
Laboratory Testing	Basic laboratory testing to include BUN/creatinine. UA and eGFR; CBC, LDH, LFTs. ALP and calcium level test may be used at the discretion of the physician; Progressive renal insufficiency should prompt a nephrology referral
CNS Scan	Acute neurological signs should undergo prompt cross sectional (CT or MRI) scan of the head or spine based on localized symptomatology
Bone Scan	Elevated ALP, clinical symptoms such as bone pain, and/or radiographic findings suggestive of a bony neoplasm should prompt a bone scan; A bone scan should not be performed in the absence of these symptoms
Percutaneous Biopsy	Percutaneous biopsy may be considered prior to active surveillance
Abdominal Scan/Imaging	Cross-sectional abdominal scanning (CT or MRI) within six months of active surveillance initiation to establish a growth rate with continued imaging (US, CT or MRI) at least annually thereafter
Chest X-ray	Patients with biopsy proven RCC or a tumour with oncocytic features on active surveillance should undergo an annual chest x-ray to assess for pulmonary metastases

Percutaneous biopsy may be considered in patients planning to undergo active surveillance.

The Panel of the AUA guidelines recommends that patients undergo cross-sectional abdominal scanning (CT or MRI) within six months of active surveillance initiation to establish a growth rate. They also recommend continued imaging (US, CT or MRI) at least annually thereafter. CT and MRI tend to be used more often for surveillance because they provides higher quality information over US, especially for neoplasms under 3cm; however, there may be benefits in reducing the risks of contrast and radiation exposure by employing alternative imaging. Alternative methods for limiting the amount of radiation and contrast exposure, include limiting CT use to once yearly unless otherwise clinically indicated, using a low dose radiation CT protocol for imaging, using MRI, and/or alternating the use of CT or MRI with US for surveillance. Importantly, with respect to tumor size measurements, differences of < 3.1 mm for inter-observer or < 2.3 mm for intra-observer evaluations are within the variability of measurement and should, therefore, not be attributed to tumor growth [20], unless in the case where there are persistent increases over two or more interval exams. Although it has been shown that the growth rate of a renal mass does not necessarily predict the presence of cancer and no robust method exists for distinguishing benign/indolent versus malignant/aggressive tumors based purely on radiologic features, more rapid rates and larger size trend towards association with true cancer and aggressive disease.

Patients on active surveillance with biopsy proven renal cell carcinoma or a tumor with oncocytic features should undergo an annual chest x-ray (CXR) to assess for pulmonary metastases.

FOLLOW-UP AFTER ABLATION THERAPY (TABLE 7)

Thermal ablative modalities, specifically cryoablation and radiofrequency ablation (RFA), currently represent accepted minimally invasive treatment options for clinical T1a renal masses in select patients with appropriate informed consent and counselling. Ablative techniques may be performed by a variety of approaches (open/laparoscopic/percutaneous) and operators (urologic surgeons/interventional radiologists). The majority of neoplasms selected for ablative procedures are less than 4 cm and exophytic, as markedly higher incomplete ablation rates have been noted for endophytic, central and larger neoplasms.

A urologist should be involved in the clinical management of all patients undergoing renal ablative procedures including percutaneous ablation. All patients undergoing ablation procedures for a renal mass should undergo a pretreatment diagnostic biopsy.

A standardized definition of treatment failure or local recurrence should be adopted by clinicians. This should be further clarified to include a visually enlarging neoplasm or new nodularity in the same area of treatment whether determined by enhancement of the neoplasm on post-treatment contrast imaging, or failure of regression in size of the treated lesion over time, new satellite or port site soft tissue nodules or biopsy proven recurrence.

Table 7. Follow-up after Ablation Therapy

Follow-up Measure	Renal Ablation
Physical Exam and History	History and physical examination directed at detecting signs and symptoms of metastatic spread or local recurrence
Laboratory Testing	Basic laboratory testing to include BUN/creatinine. UA and eGFR; CBC, LDH, LFTs. ALP and calcium level test may be used at the discretion of the physician; Progressive renal insufficiency should prompt a nephrology referral
CNS Scan	Acute neurological signs should undergo prompt cross sectional (CT or MRI) scan of the head or spine based on localized symptomatology
Bone Scan	Elevated ALP, clinical symptoms such as bone pain, and/or radiographic findings suggestive of a bony neoplasm should prompt a bone scan; A bone scan should not be performed in the absence of these symptoms
Percutaneous Biopsy	Patients should undergo a pre-treatment diagnosis biopsy
Abdominal Scan	Cross-sectional abdominal scanning (CT or MRI) with and without IV contrast unless otherwise contraindicated at three and six months following ablative therapy with continued scanning annually thereafter for five years; Scanning beyond five years is optional based on individual risk factors
Chest X-ray	Patients who have either biopsy proven low risk RCC, oncocytoma, a tumour with oncocytic features, non-diagnostic biopsies or no prior biopsy should undergo annual chest x-ray to assess for pulmonary metastases for five years; Imaging CXR or CT beyond five years is optional based on individual patient risk factors and the determination of treatment success; Radiologic scanning is not recommended with pathological confirmation of benign disease at or before treatment and post treatment radiographic confirmation of treatment success and no evidence or treatment-related complications.
Repeat Biopsy	New enhancement, a progressive increase in size of an ablated neoplasm with or without contrast enhancement, new nodularity in or around the treated zone, failure of the treated lesion to regress over time, satellite or port side lesions, should prompt a repeat lesion biopsy. Observation, repeat treatment and surgical intervention should be discussed.

Patients should undergo cross-sectional scanning (CT or MRI) with and without intravenous (IV) contrast unless otherwise contraindicated at three and six months following ablative therapy to assess treatment success. This should be followed by annual abdominal scans (CT or MRI) thereafter for five years.

Patients may undergo further scanning (CT or MRI) beyond five years based on individual patient risk factors.

Patients undergoing ablative procedures who have either biopsy proven low risk renal cell carcinoma, oncocytoma, a tumor with oncocytic features, non-diagnostic biopsies or no prior biopsy should undergo annual chest x-ray (CXR) to assess for pulmonary metastases for five years. Imaging beyond five years is optional based on individual patient risk factors and the determination of treatment success.

Patients who underwent an ablative procedure with pathological confirmation of benign histology at or before treatment and who have radiographic confirmation of treatment success and no evidence of treatment related complications don't need further imaging studies.

The alternatives of observation, repeat treatment and surgical intervention should be discussed, and repeat biopsy should be performed if there is radiographic evidence of treatment failure within six months if the patient is a treatment candidate. A progressive increase in size of an ablated neoplasm, with or without contrast enhancement, new nodularity in or around the treated zone, failure of the treated lesion to regress in size over time, satellite or port side lesions, should prompt lesion biopsy.

EVALUATION OF THE GUIDELINES AND FUTURE DIRECTIONS

In November 2014 an evaluation of the National Comprehensive Cancer Network and American Urological Association Renal Cell Carcinoma Surveillance Guidelines was presented at the American Society of Clinical Oncology 2014 Genitourinary Cancers Symposium, San Francisco, CA, January 31-February 1, 2014, and the 2014 Annual Meeting of the American Urological Association, Orlando, FL, May 16-21, 2014, and published in the Journal of Clinical Oncology [22]. 3,651 patients who underwent surgery for M0 RCC between 1970 and 2008 were stratified as AUA low risk (pT1Nx-0) after partial (LR-partial) or radical nephrectomy (LR-radical) or as moderate/high risk (M/HR; pT2-4Nx-0/pTanyN1). Guidelines were assessed by calculating the percentage of recurrences detected when following the 2013 and 2014 NCCN and AUA recommendations, and associated Medicare costs were compared. At a median follow-up of 9.0 years a total of 1,088 patients (29.8%) experienced a recurrence.

Surprisingly, nearly one third of recurrences were missed when following American Urological Association or National Comprehensive Cancer Network guidelines, with a need for significantly longer follow-up (up to 21 years) to capture 95% of these recurrences. In an editorial that accompanied that article, Angela B. Smith, MD, and Matthew I. Milowsky, MD, of the University Of North Carolina Lineberger Comprehensive Cancer Center, called the results striking, but added a few additional points to help put the results in perspective. [23]

First, they noted that the results were taken from a single center making it difficult to generalize more widely. Next, because the researchers found higher recurrence rates among

low-risk radical nephrectomy patients, physicians may lack an accurate system for characterizing low- and high-risk RCC.

Gaining a better understanding of tumor biology may improve risk stratification and translate to a surveillance regimen that more accurately captures meaningful recurrences (ie, those that require treatment, affect survival outcomes, or diminish quality of life). Without stronger data associating surveillance with survival and quality of life, justification for extending surveillance guidelines and incurring the additional cost cannot be recommended at this time.

There is a critical need for high quality, prospectively defined cohort studies to better define the prognosis of various renal masses and to establish prognosticators of important patient outcomes, such as overall survival, disease specific survival, cardiovascular and metabolic sequelae and quality of life. Given the potential burden of long-term follow-up of renal masses, randomized trials of different surveillance regimens should be conducted in order to better tailor follow-up to the patients' needs. There is a need for better prospectively designed studies to define the diagnostic accuracy of renal biopsies to define the underlying pathology, natural history and need for treatment, and also renal biopsies following ablative therapies to define the treatment response, natural history and need for further treatment. In light of the expanding use of ablative therapies for renal masses there is need for a uniform definition of treatment success and failure. There is a essential for better prospectively designed studies to examine the utility of tissue, plasma, or tumor markers or existing markers of systemic inflammation/immune response, in predicting survival, recurrence or metabolic sequelae. [11]

CONCLUSION

Follow-up after surgery, active surveillance and ablation treatment allows the urologist to monitor for postoperative complications, renal function, local recurrence, recurrence in the contralateral kidney and development of metastasis. No single follow-up plan is appropriate for all patients. There is no evidence that any particular follow-up protocol influences the outcome in early RCC. No standard recommendation can be given for the follow-up in advanced RCC either. The follow-up scheme for localised RCC following surgery should be dependent on the therapeutic possibilities upon recurrence. CT scans of thorax and abdomen are routinely performed, with time intervals dependent on risk factors. Long-term follow-up is proposed in some institutions, due to the possibility of late relapse, but its benefit has never been demonstrated. Most follow-up test after ablative therapy are similar to the test included during active surveillance. All the guidelines and recommendations should be modified for the individual patient using clinical judgment.

Current guidelines misses a significant proportion of RCC recurrences. Further research remains necessary to identify an optimal surveillance approach that balances patient benefit and health care costs.

²Medical Oncology Department, Arnau de Vilanova University Hospital of Lleida, Spain

ABSTRACT

The development of minimally invasive surgery has made a dramatic impact on all fields of surgery. Video-assisted thoracic surgery (VATS) lobectomy for early-stage non-small cell lung cancer was first described in the early 1990's and has become widely accepted for its safety and effectiveness. In addition, numerous reports have suggested favorable perioperative outcomes for this procedure, including lower morbidity, equivalent or reduced mortality, a shorter hospital stay, and an improved lung function. In carefully selected patients with early-stage lung cancer, VATS is a promising technique that reduces morbidity and promotes recovery without sacrificing the oncologic prognosis. Principle procedures, indications, short- and long-term benefit and complications of VATS lobectomy will be reviewed by comparison with conventional open lobectomy.

1. GENERAL DEFINITION OF THE PROCEDURE

The definition of video-assisted thoracic surgery (VATS) lobectomy for early-stage non-small cell lung cancer (NSCLC) is often confused with what is called Hybrid VATS, in which 'mini-thoracotomy lobectomy' is assisted by an endoscope. We prefer to standardize the definition of VATS lobectomy to encompass true anatomic lobectomy with individual ligation of the lobar vessels and bronchus as well as hilar lymph node dissection or sampling using only the video screen for guidance, with three or four ports and no retractor or rib spreading.

International standards differentiate thoracoscopic surgery and open surgery according to whether the operation is performed using a video-image system or direct visualization and not based on whether an endoscope is used for assistance.

Historically, the use of surgery with thoracoscopic procedures to treat lung diseases goes back to Sweden, 1910 when Jacobeus first reported ability to lyse tuberculous adhesions using a cystoscope. For many years, thoracoscopic procedures were chiefly used to perform biopsies and/or for diagnostic purposes, while open thoracotomy was the standard procedure to treat more extensive lesions. The first VATS lobectomy was reported by Lewis in 1992 [1]. However, the procedure was not widely accepted at that time due to a lack of evidence concerning both short- and long-term results. Lobectomy or anatomical segmentectomy is especially challenging and technically demanding, with a steep learning curve, which may discourage surgeons in smaller centers. Nevertheless, the VATS procedure has become increasingly accepted in the last two decades following advances in thoracoscopic equipment, particularly high-definition cameras and monitors. A recent meta-analysis also confirmed its validity, and VATS lobectomy is gradually becoming accepted as a standard procedure for early-stage lung cancer. Unfortunately, only 45% of lobectomies registered in the Society of Thoracic Surgeons database are performed thoracoscopically [2].

Currently, this percentage is increasing, and due to the benefits of the procedure, we feel that VATS surgery may be a valid treatment option in carefully selected patients.

The most recent guidelines on NSCLC from the National Comprehensive Cancer Network indicate that VATS lobectomy is a reasonable surgical approach for early-stage NSCLC [3]. A new section of the document states that, "in high-volume centers with significant VATS experience, VATS lobectomy in selected patients results in improved early outcomes (pain, hospital length of stay, return to function) without compromise of cancer outcomes". The guidelines of the American College of Chest Physicians (ACCP) also recommend minimally invasive approaches over thoracotomy for clinical stage I NSCLC at experienced centers [4]. Meanwhile, the European Society for Medical Oncology (ESMO) guidelines state that "either open thoracotomy or VATS access can thus be utilized as appropriate to the expertise of the surgeon".

However, caution should be taken in that there is not enough evidence from randomized controlled trials to detect important differences between the two techniques [5]. Nonetheless, the number of studies favoring VATS resection has increased in the past decade, and most guidelines accept this technique as being a reasonable procedure for treating early-stage NSCLC (Table 1).

2. INDICATIONS AND CONTRAINDICATIONS

Although the VATS procedure is beneficial as a result of minimal invasiveness, some patients may not be candidates for VATS lobectomy. The indications for VATS lobectomy as well as rules for conversion to thoracotomy vary among surgeons, readily changing over time as the surgeon gains more experience with the procedure.

The stage and minimal physiological requirements for lobectomy must be determined carefully preoperatively. This usually requires lung function testing, positron emission computed tomography scanning and bronchoscopy.

Table 1. Guidelines for video-assisted thoracic surgery in early stage non-small cell lung cancer

Guideline	Year	VATS	Grade of recommendation
NCCN	2013	VATS is a reasonable and acceptable approach for patients with no anatomic or surgical contraindications, as long as there is no compromise of standard oncologic and dissection principles of thoracic surgery	2A: Based upon lower-level evidence, there is uniform NCCn consensus that the intervention is appropriate
ACCP	2013	For patients with clinical stage I NSCLC, a minimally invasive approach such as VATS is preferred over a thoracotomy for anatomic pulmonary resection and is suggested in experienced centers	2C
ESMO	2013	Either open thoracotomy or VATS access can be utilised as appropriate to the expertise of the surgeon	3C 3: prospective cohort studies. A: Strong evidence for efficacy with a substantial clinical benefit, strongly recommended

ACCP American College of Chest Physicians; ESMO European Society of Medical Oncology; NCCN National Comprehensive Cancer Network.

The best candidates for VATS lobectomy are patients with early-stage NSCLC. The indications do not differ too much from those for open lobectomy, as the procedure inevitably involves the risk of conversion to open surgery. Therefore, peripherally located T1-2 tumors (clinical stage I) should be first considered for VATS procedures.

Although the tumor size may vary, the lesions must be small enough to be removed without having to enlarge the 3-5 cm incision for instrumentation or cause trauma to the ribs. We consider tumors up to 3 cm in size to constitute the general criterion.

T3 (chest wall) or T4 tumors, active N2-3 disease, intolerance to single-lung ventilation and the inability to achieve complete resection with lobectomy are considered to be contraindications for VATS surgery [6]. Tumors found to be visible on bronchoscopy within 2 cm of the lobar orifice should be evaluated carefully considering possible sleeve resection. Relative contraindications include tumors centrally located near the hilum or major blood vessels, involving complicated or severely calcified areas of hilar lymphadenopathy, or history of a prior irradiation. Although much attention is required in patients with prior tuberculosis infection, or subjected to cardiothoracic surgery or chemoradiotherapy, they are not necessarily contraindicated for VATS surgery. Successful VATS procedures have been reported in patients with a prior history of surgery, T3 tumors involving the pericardium or mediastinal pleura, incomplete fissures, and non-calcified adenopathy [7-9]. The procedure should be attempted in borderline cases based on the surgeon's experience.

Age is usually not a limitation for VATS surgery. Rather, reports have been published favoring VATS lobectomy in elderly patients. For example, a retrospective, matched case-control study evaluating perioperative outcomes after open surgery versus VATS lobectomy for clinical stage I NSCLC in patients over 70 years of age showed that the VATS group had a significantly lower rate of complications (28% vs. 45%), shorter length of hospital stay (5 vs. 6 days) and overall reduced severity of complications [10]. This opens the door for the use of this technique in patients previously rejected for surgical therapy due to their overall

physical status. However, aggressive attempts to continue the VATS procedure after encountering complications may be hazardous, and resection without a negative margin is not acceptable; thus, the surgeon must always keep in mind the need to convert to open surgery without delay.

3. LIGHTS AND SHADOWS

A great benefit of VATS is that the operation can be visualized by assisting doctors or nurses with the same high-quality view experienced by the surgeon. Sharing visual information of the surgical site is advantageous for teamwork and allows for better communication. This set-up is also helpful for providing education to students and residents.

Furthermore, the use of high-definition monitors is also superior to direct vision, especially in cases of thoracic surgery, where the operation is performed deep within the thoracic cavity, where light sources may have difficulty reaching.

On the other hand, a major disadvantage of VATS surgery is that neither hands-on procedures nor palpation of the diseased lesions can be performed.

As for the patient, the benefits of minimal invasive surgery are primarily based on quality of life measurements. Such factors include the postsurgical pulmonary function, pain, length of stay, overall wellbeing, and discharge independence. Table 2 summarizes complication rates from several meta-analyses. Most authors agree that complication rates are lower or equivalent to those of open lobectomy and that this advantage results in a decreased length of hospital stay. Persistent air leakage is a troublesome complication for both the patient and surgeon. In most institutions, chest tubes are removed within a few days, and data suggest a tendency toward a shorter duration to removal and lower risk of prolonged air leaks [11, 12].

Table 2. Comparison of postoperative morbidity and mortality in prior meta-analyses

Author	Publication year	Literature search	Survival rate	Perioperative mortality	Perioperative morbidity	Local recurrence	Prolonged air leakage	Arrhythmia	Pneumonia
Yan [18]	2009	21 studies (2RCT, 19RC)	VATS higher	No difference	VATS lower	VATS lower	No difference	No difference	No difference
Cao [20]	2012	4studies	NR	No difference	VATS lower	NR	VATS lower	VATS lower	VATS lower
Cai [19]	2013	23 studies (2RCT, 21RC)	VATS higher	NR	VATS lower	VATS higher	No difference	No difference	No difference
Zhang [27]	2013	21 studies (2RCT, 19RC)	VATS higher	NR	NR	VATS lower	NR	NR	NR
Taioli [28]	2013	20 studies (all RC)	VATS higher	NR	NR	NR	NR	NR	NR

NR not reported; RC retrospective cohort; RCT randomized controlled trial.

Although this complication is not necessarily life threatening, reducing the number of chest tube days shortens the hospital stay and decreases costs and stress on the patient.

Postoperative pain, usually related to the use of rib spreading during open surgery is inevitable. Proper management of persistent and substantial pain has a significant effect on the patient's recovery. Several previous groups have shown that VATS lobectomy reduces postoperative pain compared to open surgery [11, 13-16] as Cheng et al. [14] reported in their meta-analysis and systemic review of controlled trials. VATS surgery promoted a significant decrease in the dose of pain medicine and duration of intake, as evidenced by lower scores on the Visual Analog Scale.

Significant improvements in the arm and shoulder function and postoperative forced vital capacity have also been reported [14, 17]. Li et al. [17] performed a prospective study of the shoulder function, as assessed by physiotherapists using the American Shoulder and Elbow Surgeons Standardized Shoulder Assessment Form, in 29 patients undergoing either VATS or open surgery. The results showed that shoulder strength was preserved in 92% of the VATS group, compared to 81% in the open surgery group, with a better range of motion.

A recent report evaluating the Society of Thoracic Surgeons (STS) Database showed that open surgery and decreased FEV1% and DLCO% values are independent predictors of pulmonary complications. Furthermore, VATS surgery results in fewer pulmonary complications in patients with a FEV below 60% of the predicted value compared to open surgery [2]. Pneumonia is a life-threatening complication after lung surgery. Several meta-analyses have demonstrated a reduced risk of pneumonia in patients treated with VATS surgery [18-20]. Whitson et al. [11] reported a significantly fewer cases of postoperative pneumonia in clinical stage I NSCLC treated with VATS lobectomy than with open surgery, and attributed the results to a decreased acute inflammatory response and reduced sputum production. Indeed, the levels of inflammatory markers are known to be lower or not persistently elevated after VATS surgery. It has also been demonstrated that the VATS procedure induces a lower stress response than conventional surgery.

Many groups have studied inflammatory markers and immune responses after VATS surgery. Notably, Yim et al. [21] reported significantly low levels of interleukin-6 and -8 in patients undergoing thoracoscopic surgery [21]. Moreover, a study by Craig et al. showed lower levels of C-reactive protein and interleukin-6 [22].

In terms of tumor immunosurveillance, the cytotoxic function of natural killer cells plays an important role in this process. In general, the greater the surgical stress, the greater the impact on cell-mediated immunity. In one study, Ng et al. [23] found higher circulating levels of insulin-like growth factor binding protein 3 (IGFBP-3) and lower levels of matrix metalloproteinase-9 (MMP-9) and tissue inhibitor of metalloproteinase-1 (TIMP-1: antagonist of MMP-9) in the VATS group. Studies of low levels of IGFBP-3, known to be a p53-regulated apoptotic factor, have linked this finding to the advancement of various cancers and development of colon cancer in particular. Surgical trauma has also been reported to be associated with increased levels of MMP-9, which can deactivate IGFBP-3.

Taken together, the immune status and autologous tumor killing ability is better preserved with thoracoscopic surgery. These immunological benefits may also aid the smooth delivery of postoperative chemotherapy when required. Furthermore, preserving the postoperative immune function may result in a lower rate of recurrence and better prognosis.

One must not forget that the primary objective of any surgery for cancer is to perform safe, as well as complete, resection.

The Cancer and Leukemia Group B 39802 trial was performed to assess whether the use of VATS in cases of early NSCLC using a standard definition for VATS lobectomy is

reasonable, although this was a prospective, multi-institutional study [8]. In that trial, the authors defined feasibility as “the ability to successfully perform lobectomy without significant morbidity or perioperative mortality.” The consequent low rates of complications and favorable outcomes regarding the secondary survival endpoints at early follow-up demonstrated that VATS lobectomy is indeed feasible.

In addition, there are three prospective randomized trials comparing VATS lobectomy with the open approach [24-26]. The earliest study by Kirby confirmed that VATS lobectomy is not inferior to open surgery [25]. That is, the authors reported no significant differences in perioperative morbidity. More recent studies by Sugi or Palade have not only shown comparable morbidity, but also acceptable 5-year survival [24, 26].

Table 3 shows a summary of the four prospective randomized trials. There has been debate as to whether mediastinal lymphadenectomy is as effective in VATS surgery as in open surgery. A study by Palade focused on the number of lymph nodes that could be removed with each procedure and concluded that there were no significant differences regarding the overall number of lymph nodes or number of lymph nodes in each zone [26].

Oncologic effectiveness is an indispensable factor for assessing the feasibility of any treatment. Several meta-analyses comparing the efficacy of VATS lobectomy and open surgery for early-stage NSCLC have been reported [18, 19, 27, 28], and a number of comparative studies have found no significant differences in local or systemic recurrence rates [24, 29, 30]. There appears to be argument in terms of local regional recurrence rates, in which some studies have reported higher incidences [19] and others have shown either significant decreases [27] or no significant differences [18]. However, there is a consensus as to long-term mortality, as most studies provide data in favor of VATS lobectomy or show equivalent outcomes for stage I NSCLC [18, 19, 27, 28]. A meta-analysis by Taioli including 20 observational studies (2,106 VATS and 2,661 thoracotomy patients) showed an advantage in long-term mortality for patients undergoing VATS and a higher as 5-year OS when compared with subjects undergoing thoracotomy (62-97% vs. 58-97%) [28].

Table 3. Prospective randomized trials with VATS lobectomy

Author	Publication year	Purpose	Stage	N	Operative time	Number of dissected LNs	Perioperative complication	Hospital stay	Survival
Swanson [8]	2007	VATS feasibility	stage I	111	VATS feasible	VATS feasible	VATS feasible	NR	NR
Kirby [25]	1995	VATS vs. Open surgery	stage I	55	No difference	NR	No difference	No difference	NR
Sugi [24]	2000	VATS vs. Open surgery	stage I	100	NR	No difference	NR	NR	No difference
Palade [26]	2013	VATS vs. Open surgery	stage I	66	VATS longer	No difference	No difference	No difference	No difference

Furthermore, Yan reported a reduced systemic recurrence rate [18], and Cai showed similar distant recurrence rates [19]. Owing to its lower morbidity rates, VATS resection allows for more patients to receive proper doses of adjuvant chemotherapy, which maximizes curability, even in those patients treated with incomplete resection [31, 32].

This implies that VATS surgery could provide to elderly patients or fragile patients the chance of surgical curability and/or mass reduction, which may result in better results in association with adjuvant chemotherapy. In terms of medical economics, the cost of disposable instruments, such as endoscopic staplers, is often associated with increased expenses for minimally invasive surgeries. However, some authors have argued that the overall hospital charge for VATS surgery may be lower due to the shorter length of hospital stay and, although not always applicable, reduced number of days in the intensive care unit [33]. Swanson et al. [34] performed a retrospective multi-institutional database analysis of 3,961 patients (including 2,907 open resections and 1,054 VATS) undergoing lobectomy for cancer [34] and found that hospital costs were higher in the open surgery group than in the VATS group (\$21,016 vs. \$20,316).

More interestingly, adjusting for the surgeon's experience revealed the average cost for surgery performed by experienced surgeons to be significantly lower.

4. PROCEDURE

A preoperative evaluation of the lung tumor and workup of the patient's physical status must be conducted, similar to conventional resection. A major disadvantage of VATS surgery is that the surgeon cannot palpate the tumor. Therefore, performing imaging of the lesion preoperatively is crucial for successfully completing the procedure. Three-dimensional computed tomography can be applied to evaluate the tumor location and pulmonary vessel branching pattern, increasing the safety of VATS surgery [35].

A typical operating room set-up is shown in Figure 1. The anesthetic technique for VATS lobectomy is similar to that applied in other cases of pulmonary resection, and the use of a double lumen endotracheal tube or bronchial blocker is routine to obtain single lung ventilation. The patient is placed in the lateral decubitus position, which helps to spread the intercostal space and provides a good operative field. The number and placement of port incisions vary according to the preference and experience of the surgeon.

In general, the port positions are the same whether upper, lower or middle lobectomy is performed. The placement of the camera and working ports is crucial for successfully completing the procedure. In our facility, the location of the port differs between operations involving the right and left lung.

The position of the port during the operation for the right and left lungs is shown in Figure 2. The surgeon is positioned on the right side of the patient, while the scopist and the assistant are positioned on the left side of the patient.

Two video monitors are positioned cranially on both sides of the patient. All thoracoscopic surgeries are performed with a 10- or 5-mm 30-degree angled thoracoscope. Instrumentation is important when performing thoracoscopic pulmonary resection, and the selection of fine instruments with an appropriate reach is mandatory for retraction and dissection.

Figure 1. A typical operating room set-up.

¹3-5 cm incision with the wound protector for surgeon's hand instrument.

²10 mm working port for the surgeon's left instrument.

³10 mm camera port.

⁴15 mm port for the assistant's instrument.

Figure 2. Typical positioning of incisions for VATS surgery.

High-definition video equipment improves visualization in cases of difficult dissection. The pulmonary vessels and bronchi are dissected as in open thoracotomy. The vessels, bronchus and fissures are divided sequentially using appropriate endo-staplers. Sometimes, the vessel sealing system is applied for small vessels measuring 3-4 mm in diameter.

This is very useful for lymphadenectomy, where the system facilitates "en bloc" dissection. The resected lobe is placed in a protective plastic bag and removed through the incision at which the ribs are widest. Finally, a single chest tube is placed intercostally towards the apex through the assistant's instrument incision.

5. SAFETY AND COMPLICATIONS

The safety and efficacy of VATS lobectomy has been demonstrated in several reviews worldwide. However, in order to perform VATS surgery safely, the surgeon must always keep a watchful eye on the potential for complications and be ready for conversion to open surgery. In a series of 1,806 patients planned to undergo VATS lobectomy, Yang reported major complications in 129 patients (7.3%), with a mortality rate of 0.3%. The authors found that pulmonary complications, including prolonged air leaks, atelectasis and pleural effusion, contributed to more than 90% of the major complications and 80% of mortality. Furthermore, a multivariate logistic regression analysis showed that co-morbidity and a long operative time longer than 240 minutes were independent risk factors for major adverse events [36]. However, this is not to say that the complication rates are high compared to open surgery. A retrospective study by Whitson et al. [37] analyzed 147 patients with clinical stage I NSCLC, including 88 cases of thoracotomy and 59 cases of VATS surgery, reporting that no significant differences in terms of perioperative complications such as the operative time, amount of blood loss, incidence of atrial fibrillation, or number of ventilator days between both two groups. Meta-analyses comparing the two procedures have also provided data showing lower or at least equivalent morbidity, as mentioned earlier.

The rate of conversion to open surgery is reported to be 0-17% [18]. According to Hanna et al. [6], the causes of conversion to open thoracotomy can be classified into four categories: intraoperative complications, technical problems, anatomical problems, and the oncological condition. Some reported reasons for conversion include the tumor location, bleeding, dense lymphadenopathy, presence of calcified nodes adhering to the pulmonary arteries and bronchus, history of tuberculosis, intolerance to single-lung ventilation, an abnormal bronchial anatomy, the inability to identify pathological areas, difficulty in safely dissecting the interlobular pulmonary artery or the detection of incomplete fissures. Converted VATS procedures have been reported to result in an increased risk of postoperative atrial fibrillation, length of stay, duration of chest tube drainage, operative time and amount of intraoperative blood loss [38], and, although the VATS procedure is primarily indicated for most early-stage NSCLC lesions, cases involving calcification near the hilum should only be considered by surgeons with adequate experience. Haraguchi used receiver-operator characteristic curves to analyze risk factors for VATS and found that an operative time lasting for more than 297 minutes cancels out the advantages of VATS surgery [39]. This implies that the initial judgment as to the indication for VATS is vital and that any delays in the decision regarding conversion to open surgery may compromise patient outcomes.

CONCLUSION

The safety and efficacy of thoracoscopic lobectomy have been gradually recognized and are becoming widely accepted. Many studies have reported findings showing reduced chest wall trauma, an improved pulmonary function and lower levels of cytokine dysfunction.

Furthermore, patients who require chemotherapy after VATS surgery are more likely to succeed in completing the prescribed course of chemotherapy. From the standpoint of medical economics, these better outcomes are thought to contribute to significant hospital

savings. Unfortunately, randomized trials comparing the oncologic efficacy of VATS and open approaches remain insufficient, and the further accumulation of evidence supporting the advantages of VATS is expected to advance the rate of adoption of VATS procedures for early-stage NSCLC.

ABSTRACT

At present, the standard treatment modality for early-stage non-small cell lung cancer (NSCLC) is lobectomy or any other form of resection of the affected pulmonary parenchyma and mediastinal lymph node removal. The recent progress in the diagnostic modalities including high-resolution computed tomography or fluorodeoxyglucose positron emission tomography have enabled oncologists to obtain a more accurate clinical diagnosis at the time of treatment. Simultaneously, a greater number of small-sized lung cancers are also being detected. The presence of ground-glass opacity nodules in the lung cancer has suggested a prognostic factor for post-operative survival, especially for tumors greater than 2 cm.

Subsequently, arguments for the surgical procedure of choice for such small-sized lung cancers, i.e. sublobar resection or lobectomy, have emerged. Based on the results of the phase III trial conducted in 1995, lobectomy and mediastinal lymph node dissection is the standard procedure for early-stage NSCLC. On the contrary, many articles support or oppose the benefits of sublobar resection over lobectomy on post-operative pulmonary function and equivalent post-operative survival. There has not been any conclusive evidence to resolve this issue, as there is no phase III trial directly comparing sublobar resection with lobar resection for early-stage NSCLC, except for the one carried out during the 1980's and reported in 1995.

Two ongoing randomized phase III trials by the Japanese Clinical Oncology Group and the West Japan Oncology Group (JCOG0802/WJOG4607L) and by Cancer and Leukemia Group B of the United States (CALGB 140503) will compare sublobar resection with lobectomy, which will hopefully provide the answers. Stage II NSCLC include a more heterogeneous group of tumors with aspects such as the more frequent hilar lymph node metastasis and a more aggressive nature of the primary tumor.

Therefore, lobectomy or another form of resection with removal of mediastinal lymph node is often appropriate for treating them. The large-size of primary tumor involvement or the central bronchus or hilar node metastasis sometimes requires pneumonectomy. Plasty of bronchus and/or pulmonary artery is selected to preserve the post-operative pulmonary function. Adjuvant chemotherapy is currently standard treatment of choice following resection.

1. HISTORY OF PULMONARY RESECTION

Surgical treatments for lung cancer have greatly improved and become widespread during the last five decades. The first ever successful pulmonary lobectomy was performed in 1912 by Davies [1] in a patient with pulmonary tumor, the patient survived for eight years after the operation. Subsequently, the first successful one-stage pneumonectomy for a lung cancer patient was reported by Graham in 1933 [2]. The first successful anatomical segmentectomy for a patient with bronchiectasis was performed by Churchill and Belsey in 1939 [3]. In 1960, Cahan [4] established lobectomy with mediastinal lymph node dissection as the standard surgical procedure for lung cancer treatment.

2. CLINICAL FEATURE OF EARLY-STAGE NON-SMALL CELL LUNG CANCER: THE SEVENTH TNM STAGING VERSION

Lung cancer is the leading cause of death among adults worldwide. The estimated numbers of new cases and deaths due to lung cancer in the United States in 2014 were 224,210 and 159,260 respectively. The five-year survival rate was 17% for patients in all stages and 54% for localized disease only [5].

The definition of stage I-II lung cancer in tumor, node, metastasis (TNM) 7th staging version is summarized in Table 1 [6]. Briefly, stage I cancer can be defined as lung cancer without lymph node involvement. They are sub-classified according to tumor size into stage IA (less than 3 cm) and stage IB (3-5 cm). Stage II includes T2 tumor involving the main bronchus ≥ 2 cm distal to the carina, invading the visceral pleura, or associated with atelectasis or obstructive pneumonitis that extends to the hilar region, but not involving the entire lung. Stage II cancer is also sub-classified into stage IIA and Stage IIB. Stage IIA cancer includes smaller than 5 cm tumors (T1-2a) with hilar lymph node involvement (N1) or tumor sized 5-7 cm (T2b) without lymph node metastases. Stage IIB includes T2b tumors with hilar lymph node metastases or tumor longer than 7 cm or directly invading any of the following: 1) chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, and parietal pericardium; 2) tumor in the main bronchus closer than 2 cm distal to the carina but not involving it; 3) associated atelectasis or obstructive pneumonitis of the entire lung, or; 4) separate tumor nodule(s) in the same lobe (T3).

Table 1. Features of Stage I-II lung cancer defined by Seventh tumor, node, metastasis classification of lung cancer

Stage	
IA	T1a-bN0
IB	T2aN0
IIA	T1a-T2aN1
	T2bN0
IIB	T2bN1
	T3N0 (any T3)
Definitions	
T: Tumor	
Tumor < 3 cm in greatest dimension, surrounded by lung or visceral pleura, without	
T1	bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)
T1a Tumor < 2 cm in greatest dimension	
T1b Tumor > 2 cm but < 3 cm in greatest dimension	
T2 Tumor > 3 cm but < 7 cm or tumor with any of the following features (T2 tumors with these features are classified T2a if < 5 cm):	
Involves main bronchus, > 2 cm distal to the carina	
Invades visceral pleura	
Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung	
T2a Tumor > 3 cm but < 5 cm in greatest dimension	
T2b Tumor > 5 cm but < 7 cm in greatest dimension	
T3 Tumor > 7 cm or one that directly invades any of the following:	
Chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium	
Tumor in the main bronchus < 2 cm distal to the carina but without involvement of the carina	
Associated atelectasis or obstructive pneumonitis of the entire lung	
Separate tumor nodule(s) in the same lobe	
N: Nodes	
NX Regional lymph nodes cannot be assessed	
N0 No regional lymph node metastasis	
N1 Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension	

3. CURRENT STANDARD TREATMENT FOR CLINICAL STAGE I-II NON-SMALL CELL LUNG CANCER

To date, the standard clinical guideline for patients with clinical stage cI-II NSCLC is surgery with curative intent and lobectomy or pneumonectomy with mediastinal lymph node dissection is the recommendation (Table 2) [7-10]. The guidelines also recommend a limited lung resection only for cI-II NSCLC patients with poor pulmonary function.

This surgical strategy is based on the results of phase III trial reported by the Lung Cancer Study Group (LCSG) [11] in 1995. The primary endpoint was 5-year overall survival (OS), and the secondary endpoints were disease-free survival (DFS), post-operative pulmonary function, and patterns of recurrence. Out of the 771 patients included in the trial, 495 were found to be ineligible. Of the 276 patients found eligible, 122 patients were

randomized to limited resection group (82 patients underwent segmentectomy and 40 patients underwent partial resection), and 125 patients were allocated to the lobectomy group. Limited resection was associated with 30% increase in the overall death rate and 75% increase in recurrence rate.

Table 2. Guideline recommendations for treating early-stage lung cancer

Guideline Year		cStage	Surgery	Adjuvant CTx	
				pStage	Recommendation
NCCN7	2013	I-II	-anatomical resection (2A)	IA	-Observation (2A)
			-Segmentectomy or wedge	IB	-Observation, or CTx
			resection is appropriate in		for high risk cases (2A)
			selected patients	II	-CTx (P-based) (2A)
				IIIA	-CRT (2A)
ACCP8	2013	I-II	-Lobectomy (1B)	IA-B	-No CTx (1B)
			-LN dissection (1B)	IIA-B	-CTx (P-based) (1A)
			-Sleeve over Pneu (2C)		
ESMO9	2013	I-III	-Lobectomy (I, A)	IA	-Observation (II, B)
			-LN dissection (III, A)	II-III	-CTx (P-based) (1A)
Thorax10	2010	NS	-Sublobar resection for	IB	-CTx (B)
			limited function (B)	II-IIIA	-CTx (A)
			-Systemic dissection (A)		

CTx: chemotherapy, P-based: platinum based, CRT: chemoradiotherapy, Pneu: pneumonectomy, NS: not stated, Categories of evidence and consensus of each guidelines in parenthesis.

4. RECURRENCE PATTERN OF RESECTED EARLY-STAGE NON-SMALL CELL LUNG CANCER

Even completely resected pathological stage pI NSCLC present a 15-40% distant and 5-32% local relapse rate [12, 13]. The Lung Adjuvant Cisplatin Evaluation (LACE) meta-analysis reviewed the outcome of curatively resected pII-III NSCLC receiving adjuvant cisplatin plus vinorelbine in major phase III clinical trials (Adjuvant Navelbine International Trialist Association [14], BIG Lung Trial [15], International Adjuvant Lung Cancer Trial [16], and National Cancer Institute of Canada Clinical Trials Group JBR.10 [17]). Adjuvant chemotherapy achieved 8.9% benefit on 5-year OS compared to observation alone, and was established as standard treatment for curatively resected pII-III NSCLC patients [18].

4.1. Survival Outcome of Early Non-Small Cell Lung Cancer

In 2007, the International Staging Committee and Participating Institutions and International Association for the Study of Lung Cancer (IASLC) reported the post-operative outcome of 67,725 NSCLC treated between 1990 and 2000. Stratified by clinical stage, the 5-year OS was 50% for cIA, 43% for cIB, 36% for cIIA, and 25% for cIIB. Stratified by

pathologic stage, post-operative 5-year OS was 73% for pIA, 58% for pIB, 46% for pIIA, and 36% for pIIB [6] (Table 3).

Table 3. Improvement of post-operative 5-year survival of Stage I-II NSCLC by era

IASLC: International Association for the Study of Lung Cancer, JJCLCR: the Japanese Joint Committee of Lung Cancer Registry.

The remarkable progression and spread of current diagnostic tools such as high resolution computed tomography (CT-scan), positron emission tomography (PET/CT-scan) or magnetic resonance imaging (MRI) for lung cancer diagnosis provided an accurate baseline staging of NSCLC.

Recently data reported by the Japanese Joint Committee of Lung Cancer (JJCLCR) analyzed 11,663 resected NSCLC patients [19] (Table 3). The 5-year post-operative OS improved over time from 1994 to 2004, being 82% for cStage IA, 66% for cIB, 55% for cIIA, and 46% for cIIB tumors. The 5-year OS stratified by pathological stage was 87% for pIA, 74% for pIB, 62% for pIIA, and 60% for pIIB tumors.

4.2. Prognostic Risk Factors in Completely Resected Early-Stage Non-Small Cell Lung Cancer

Several prognostic factors have been retrospectively examined for completely resected early-stage NSCLC. Pre-operative adverse prognostic included poor performance status [20], presence of clinical symptoms [20], older age [13], pre-operative smoking history [21, 22], high serum carcinoembryonic antigen level [23], higher standardized uptake value (SUV) on PET/CT-Scan [24], tumor size [6, 23] or consolidation or tumor ratio on high resolution CT-scan [25, 26].

Surgical prognostic factors include the eventual adverse impact of positive pleural lavage fluid cytology for the lung cancer cells at the time of thoracotomy [27, 28]. No prospective clinical trial exploring this issue has been reported. However, a meta-analysis by the International Pleural Lavage Cytology Collaborators (IPLCC) including 8,763 NSCLC patients from 11 centers reported that the positive pleural lavage fluid cytology was an independent predictor of poor survival (HR 1.46; $p < 0.001$) for lung cancer patients [29]. The

role of the systemic mediastinal lymph node dissection is under discussion. In general, systemic mediastinal lymph node dissection was considered to be a favorable prognostic factor [30]. However, a recent prospective phase III clinical trial comparing the systemic mediastinal lymph node dissection with sampling alone did not revealed any differences on OS [31]. The survival benefits of lobar resection or sublobar resection including segmentectomy, especially for small-sized peripheral lung cancer, will be described below.

Pathological prognostic adverse factors included poor or moderate histological differentiation [23] or solid-predominant adenocarcinoma as per the current classification system of the International Association for the Study of Lung Cancer, American Thoracic Society (ATS) or European Respiratory Society (ERS) [32].

The so-called type A and B , less than 2 cm adenocarcinoma *in situ* in Noguchi's classification have a 5-year OS of 100% [33]. Lymphovascular invasion in the pathological specimen is not reflected in the current TNM staging. However, it has been extensively reported as a poor prognostic factor [13, 23, 34-36]. A recent meta-analysis of 20 published reports reported that lymphovascular invasion in cI NSCLC was significantly associated with a worse DFS (HR 3.63) and OS (HR 2.38) [37].

5. INTENTIONAL LIMITED RESECTION FOR EARLY-STAGE NON-SMALL CELL LUNG CANCER

As mentioned above, lobectomy has been the standard surgical procedure for the treatment of early-stage lung cancer since Lung Cancer Study Group phase III trial was published. This trial is the only randomized clinical trial directly comparing limited resection with lobectomy. Sublobar resection including segmentectomy or non-anatomical wedge resection was considered appropriate procedures for patients with insufficient pulmonary reserve for lobectomy or with any other major comorbidity. With the current developments and use of high resolution CT-scans for diagnosis, there has been an increase in the detection of small-sized NSCLC. Nevertheless, many currently detected nodules with or without ground-glass opacity (GGO) should not be detected on the plain chest roentgenography or in the Lung Cancer Study Group trial. The re-evaluation of the role of sublobar resection over lobectomy is becoming necessary. In the last two decades, numerous works have compared sublobar resection and lobectomy for early-stage NSCLC, mainly with regard to the post-operative prognosis or pulmonary function.

Segmentectomy is expected to preserve post-operative pulmonary function with lesser incidence of post-operative complications than lobectomy. Moreover, the post-operative local recurrence and survival rates have to be evaluated. Non-anatomical wedge resections are not able to evaluate hilar lymph node involvement. In segmentectomy, intraoperative frozen section is mandatory to evaluate presence of hilar lymph node metastases that warrant to convert segmentectomy to lobectomy.

Table 4 summarizes some reported articles assessing the similar prognosis and disease recurrence rate of sublobar resection when compared to lobectomy in cI NSCLC [38-42], especially in the local site. However, Okada et al. [38] compared 305 segmentectomy with 262 lobectomy cases in smaller than 2 cm peripheral cT1aN0M0 NSCLC in a non-randomized multicenter study. The 5-year local recurrence rate trended to benefit the

segmentectomy arm (4.9% vs. 6.9%), but OS was similar in both groups (89.6% vs. 89.1%). Carr et al. [39] retrospectively analyzed 178 segmentectomy and 251 lobectomy cases for cIA NSCLC. The cancer-specific 5-year OS was similar in the two arms for T1a (90% vs. 91%) and T1b tumors (82% vs. 78%). Moreover, no statistical difference was observed in the recurrence rate and operative mortality. Altorki et al. [40] compared 53 sublobar resection cases (16 segmentectomy and 37 non-anatomical wedge resection cases) with 294 lobectomy cases for mainly smaller than 2 cm cIA NSCLC. The 10-year OS was similar in both two groups (86% vs. 85%).

Table 4. Results of retrospective analysis of limited vs. lobar resection for clinical Stage I non-small cell lung cancer

Author	Year	T	Procedure	No	Rec (local/dis) (%)	5-y OS (%)
Okada M ³⁸	2005	T1a	Sublobar	305	4.9 / 9.2 ^{NS}	89.6 ^{NS}

			Lobectomy	800	5.1 / 11.6	60

Rec: recurrence, dis: distant, OS: overall survival, NS: not significant, NA: not available.

Landreneau et al. [41] also reported no significant differences in the 5-year local recurrence rate (5.5% vs. 5.1%) or OS (54% vs. 60%), even including 22% of cIB NSCLC. On the contrary, El-Sherif et al. [42] analyzed 207 sublobar (85 segmentectomy cases and 122 non-anatomical wedge resection cases) and 577 lobectomy cases for cI NSCLC including 50% of cIB patients. There was no statistical difference in DFS (HR 1.51; p= 0.0023). However, the 5-year OS was worse in segmentectomy group (40% vs. 54%; p< 0.0038). Similarly, the Surveillance Epidemiology and End Results (SEER) [43] compared the sublobar resection with lobectomy in 13,892 NSCLC. The 581 patients undergoing segmentectomy for stage IA adenocarcinoma or squamous cell carcinoma had a worse 5-year OS than those undergoing lobectomy (HR 0.73). From the same database, Yendamuri et al. [44] analyzed 2,161 patients who underwent sublobar resection and 6,636 patients who underwent lobectomy or other forms of resection, grouping the patients into three groups according to the era: 1) early, from 1987 to 1997); 2) intermediate, from 1998 to 2004), and; 3) late, from 2005 to 2008. Despite the worse prognosis in patients undergoing sublobar resection in the early period (HR 1.41), no significant difference on survival between sublobar resection and lobectomy was reported in the intermediate or late period (HR 1.04 and HR 0.83, respectively).

Despite on data supporting sublobar resection for cI NSCLC, conclusions have yet to be drawn. Causes to explain the dearth of non-randomized studies analyzing this issue included the heterogeneity of cohort groups even in the cI NSCLC (tumor size, histological subtype,

presence of adenocarcinoma *in situ*, minimally invasive adenocarcinoma [32], or GGO), and the detection of really early lesions with high resolution CT-scan or PET/CT-scan.

6. MANAGEMENT OF PULMONARY NODULES WITH GROUND-GLASS OPACITY LESIONS

With the progress and spread of CT-scan screening for lung cancer detection and the development of high resolution CT-scans, small-sized lung cancers, especially adenocarcinoma presenting GGO, are becoming more common to diagnose [45, 46]. Radiologically, GGO is defined as lesions showing hazy increased attenuation that does not obliterate the underlying bronchial or vascular structures on high resolution CT-scan [47].

Figure 1. Features of small-sized lung nodules of ground-glass opacity. (a) small-sized lung adenocarcinoma with consolidation in high resolution CT-scan. (b) mixed ground-glass opacity (c) pure ground-glass opacity.

Figure 1 shows the typical features of small-sized lung nodules of GGO with or without any consolidation detected on high resolution CT-scan and pathological specimens. Figure 1(a) shows a small-sized lung adenocarcinoma with consolidation, so-called solid nodules viewed in high resolution CT-scan. These nodules are generally defined as pathologically invasive lung cancer with a higher possibility to be detected by the plain chest roentgenogram. On the contrary, the small-sized lung nodules with solid part surrounded by GGO (mixed-GGO) or pure GGO are presented in Figures 1(b) and (c) respectively, and are often detected only by high resolution CT-scans.

6.1. Management of Focal Pure Ground-Glass Opacity Lesions

The incidence of focal pure GGO nodules has been reported to range from 6 to 12% of all CT-scan detected pulmonary nodules in the screening setting [45, 46]. Many clinicians face difficulty in treating patients with asymptomatic pulmonary nodules. The reasons for this are as follows: 1) The clinical course of focal pure GGO nodules is generally thought to be indolent [48] 2) obtaining a radiological diagnosis of these lesions is quite difficult; PET/CT-scan fails to distinguish focal pure GGO nodules from malignant tumors [49, 50], 3) the small size of focal pure GGO makes it difficult for fiberoptic bronchoscopy- or CT-scan-guided biopsies, and surgical resection alone provides the eventual diagnosis [51], and 4) the radiological-pathological concordance of focal pure GGO nodules is non-specific [52, 53].

No such definitive strategy for the management of focal pure GGO nodules exists. One possible recommendation would be the careful observation by high resolution CT-scan. The indications for surgical resection should include a tumor size greater than 10 mm and/or the development of a solid pattern in the tumor while on the follow-up [52]. Nevertheless, the adequate surgical procedure has not been clearly defined too.

6.2. Stage I Non-Small Cell Lung Cancers Presenting Part-Solid or Solid Lesions on High Resolution CT-Scan

The ratio of GGO in small-sized CT-scan detected lung cancer has been reported to predict the histological invasiveness of lung adenocarcinomas [54, 55], even in small-sized lung cancer. Figure 2 shows a mixed GGO on high resolution CT-scan. Figure 2(a) indicates the maximal diameter of the tumor, and (b) Indicates maximal diameter of the consolidation portions, thus $(b)/(a) = \text{consolidation/tumor ratio (C/T)}$. For small-sized lung cancer, especially adenocarcinoma, $C/T \leq 0.5$ is a predictor of pathologically non-invasive adenocarcinoma. A prospective analysis by the Japanese Clinical Oncology Group, the JCOG 0201 trial, analyzed the concordance between radiological findings in high resolution CT-scan and pathological non-invasiveness in 545 peripheral cIA NSCLC undergoing lobectomy along with lymph node dissection. Specificity and sensitivity were recorded to be 96.4% and 30.4%, respectively. Concordance was found to be within the specificity of 98.7% for the smaller than 2 cm tumors and $C/T < 0.25$. Thus, the non-invasive adenocarcinoma could be defined radiographically in this cohort of patients [56]. Consecutively, prognosis was evaluated in the same cohort of 545 patients from the JCOG 0201 trial revealing an significantly higher 5-year OS in cT1a-b cIA adenocarcinomas with consolidation/tumor ratio ≤ 0.5 than in those with the $C/T > 0.5$ (96.7% vs. 88.9%; $p < 0.001$). Patients with smaller than 2 cm tumors did not present any statistical difference in the 5-year OS stratified with the cut-off value ≤ 0.25 (97.1% vs. 92.4%; $p = 0.259$). Patients with $C/T < 0.25$ and smaller than 2 cm tumors and $C/T \leq 0.5$ and smaller than 3 cm tumors were considered as a homogeneous cohort with a similar 5-year OS of 97% [25].

Two ongoing prospective randomized phase III trials will assess the role of sublobar resection versus lobectomy for peripheral cIA NSCLC in Japan and the United States (Table 5). One is being conducted as an intergroup study by the Japanese Clinical Oncology Group and West Japan Oncology Group (WJOG) (JCOG0802/WJOG4607L), and the other one is being conducted by the Cancer and Leukemia Group B (CALGB 140503). The Japanese trial

plan to accrue 1,100 patients with smaller than 2 cm tumors and C/T ≥ 0.5 . OS is considered to be the primary endpoint. CALGB 140503 plan to accrue 908 patients with smaller than 2 cm tumors. These trials could shift the paradigm for the treatment strategy in cT1a IA NSCLC.

Figure 2. Mixed ground-glass opacity on high resolution CT-scan. (a) maximal diameter of the tumor. (b) maximal diameter of the consolidation portions, thus (b)/(a) = consolidation/tumor ratio.

Table 5. Ongoing prospective randomized phase III trials comparing sublobar resection vs. lobectomy

	JCOG0802/WJOG4607L	CALGB 140503
Target accrual	1,100	908
Design	Phase III, non-inferiority	Phase III, non-inferiority
Surgical procedure		
Control arm	Lobectomy	Lobectomy
Study arm	Segmentectomy	Segmentectomy or Wedge
Eligibility criteria		
T factor	peripheral, <2 cm	peripheral, <2 cm
	Part-solid (C/T ratio > 50%)	
	Single lesion	
N factor	N0	N0
Primary endpoint	OS	DFS
Secondary endpoints	Pulmonary function at 6m and 1y, DFS, LRR, AE completion rate of segmentectomy others	OS, LRR, SRR
		Pulmonary function at 6m others
Follow-up	Chest CT every 6m for 2y,	Chest CT 6m and 1y,
	then yearly until 5y	then yearly until 5y

Wedge: wedge resection, C/G: consolidation/ground-glass opacity ratio, OS: overall survival, DFS: disease free survival, LRR: local recurrence rate, SRR: systemic recurrence rate, AE: adverse event.

7. SURGERY FOR cT2-3N1M0 STAGE II NON-SMALL CELL LUNG CANCER

Surgical options for cII NSCLC are more limited due to common the hilar lymph node involvement and oncological aggressiveness. There is relative consensus for lobectomy or other resection procedures with mediastinal lymph node removal as a curative-intent resection. The extent of surgical resection is not defined. The extra-nodal invasion of the hilar lymph node to the proximal or main stem of the bronchus or segmental pulmonary artery or larger tumor > 7cm that crosses the fissure between the upper and lower lobes often requires pneumonectomy for complete resection. In selected cases, pneumonectomy with resection of carina is indicated for cT3N0 tumors invading the main bronchus within <2 cm from the carina and no lymph node invasion. The sleeve bronchial and/or pulmonary artery resection is often considered for normal pulmonary parenchyma preservation if the tumor or hilar metastatic lymph nodes invades the adjacent main bronchi or central branch of pulmonary artery. The benefit of sleeve resection over pneumonectomy is unclear. However, several articles reported equivalent post-operative survival of sleeve resection as compared to pneumonectomy [57-59] with a similar incidence morbidity or mortality [60] and better post-operative quality of life [61].

Chapter 374

VASCULAR ANATOMY OF THE SELLAR REGION AND COMPLICATIONS DURING ENDOSCOPIC ENDONASAL TRANSPHENOIDAL SURGERY FOR PITUITARY ADENOMAS

Yasuhiko Hayashi*, MD, PhD

Department of Neurosurgery, Graduate School of Medical Science,
Kanazawa University, Kanazawa, Japan

ABSTRACT

In general, transsphenoidal surgery has been considered to have a low rate of complication and mortality. Among the postoperative complications associated with transsphenoidal surgery (TSS), such as cerebrospinal fluid leakage, hypopituitarism, diabetes insipidus, vascular injury, meningitis, cranial nerve neuropathy, and nasal bleeding, vascular injury is unusual, but most possibly fatal complication. Therefore, the pituitary neurosurgeons need to have the knowledge about the possible incidence during the intra- and post-operative phase. Vascular injuries during the TSS described in the literature include fatal hemorrhage from internal carotid artery (ICA), ICA occlusion, pseudoaneurysm formation, carotid cavernous fistula, subarachnoid hemorrhage, vasospasm, and distal embolism with cerebral infarction. It is important to understand the patient's vascular anatomy at the sella and its surrounding structures, during the preoperative examination of the TSS, to avoid the vascular complications. Although recent advancement of the operative techniques and instruments of transsphenoidal approach enable the neurosurgeons to dissect arteries derived from the ICA and external carotid artery (ECA) during the surgery, it remains a difficult problem to preserve intact vessels even for the expert pituitary neurosurgeons. In particular, the introduction of endoscope into the TSS dramatically improved intraoperative visualization and diminished traumatization. Subsequently, the operative indication for performing TSS gradually developed to include the suprasellar, parasellar, clival, and cervicomedullary junction (extended transsphenoidal surgery). However, since the indications for the use of TSS have grown, this fact can lead to increasing chances of intraoperative vascular

* Corresponding Author's Email: yahayashi@med.kanazawa-u.ac.jp; Fax: +81-076-234-4262.

injuries, and till now has not been reached a definite conclusion, whether TSS has a significant difference in the complication rate between endoscope and microscope techniques. Another advancement of preoperative neuroradiological investigation to detect such arteries derived from the ICA and the ECA is also useful for their precise localization and avoidance of fatal complications. Especially, the role of digital subtraction angiography in the operating room is significant, because, once the arterial injury during TSS happens, the emergent detection of affected vessel(s) and the management of the trauma is required. In addition, the development of endovascular surgery both in the techniques and the instruments remarkably changed the principles of treatment for intraoperative vascular injury during the TSS. Especially, in cases of ICA injury, the endovascular treatment with parent artery occlusion can be performed with acceptable morbidity and mortality rates. This technique can be also applied to the pseudoaneurysm, which arises from the injury site of the ICA at the postoperative delayed period, and causes fatal and massive epistaxis. However, vascular injury during endoscopic endonasal TSS is not well studied or reported, despite it is still a feared complication. The anatomic substrate for such complication in each stage of the TSS (naso-sphenoidal, spheno-planum, dural, intrasellar, and suprasellar phase) is discussed with respect to operative and neuroradiological aspects, identification of risk factors, management strategies for avoidance of such serious vascular complications, and their outcomes.

Keywords: transsphenoidal surgery, pituitary, vascular, complication, endoscope

1. INTRODUCTION

Pituitary adenomas constitute approximately 10-22.5% of all primary intracranial tumors, and surgical removal is the first optional management except for prolactinoma [1-4]. The transsphenoidal surgery (TSS) for removal of pituitary tumors has been originally applied due to its effectiveness and safety, with serious morbidity and mortality rates typically less than 1% [5, 6]. Recent advancement in operative and neuroradiological technologies has had a major impact on the treatment strategies for pituitary tumors, and TSS has become increasingly popular all over the world. In particular, the introduction of endoscope into the TSS has made a great progress not only on the resection rate of the tumor but also on the preservation of normal endocrinological function and the remission rate for the functioning adenoma [1, 7-9]. Moreover, the indication for the use of TSS has grown for the suprasellar, parasellar, clival, and craniocervical junction, since it has been regarded as extended TSS, and many surgeons reported its effectiveness in the management of craniopharyngioma, clival chordoma, and pituitary adenoma with invasion into the cavernous sinus [10-12].

Historically, the TSS was originally introduced by Schloffer and Cushing during the first decade of the 20th Century [13-15]. The adaptation of the transsphenoidal route as a surgical corridor is based on the concept that this surgery is significantly less dangerous for the patients with pituitary tumors compared to the craniotomy, which was considered to be extraordinary difficult on the contrary, because the instrumentation, lightning, cautery, anesthesia, and medication were not available in those days [13, 14]. This revolutionary introduction was followed by the addition of the radiofluoroscopy by Guiot, as well as the operating microscope and specialized instruments by Hardy 60 years later [16, 17]. Therefore, concerning TSS, safety should be secured both through the operation by the surgical

techniques and the anatomical knowledge of the pituitary region. However, many authors have reported various complications associated with the TSS including cerebrospinal fluid leakage, hypopituitarism, diabetes insipidus, meningitis, cranial nerve neuropathy, nasal bleeding, and vascular injury [1-7, 16, 18].

Despite the advancement of TSS, one of the most serious problems during this approach is vascular complications, in which injury to the cavernous ICA most commonly occurs at the sellar dural incision, and has been reported to occur in 0-3.8% of cases [5, 18-22]. Even expert pituitary neurosurgeons experienced a 0.6-0.8% incidence of vascular injuries [23-25]. Therefore, all neurosurgeons trying to perform TSS should try to avoid the ICA injury and prepare to manage its risk with the appropriate preoperative evaluation, such as digital subtraction angiography (DSA) or 3-dimensional computed tomographic angiography (3D-CTA), fusion images with magnetic resonance imaging (MRI) and 3D-CTA, and computer graphics. The overall incidence of ICA injury was reported to be 1.1%, and the rate of ICA injury was inversely proportional to the surgeon's transsphenoidal experience, being 1.4% for the least experienced surgeons, 0.6% for those with intermediate experience, and 0.4% for the most experienced [19].

Anatomical studies of the sphenoid sinus and sellar region are relevant, because they can improve spatial orientation to the landmarks. Injury to ICA is the most feared complication leading to the catastrophic clinical deterioration of the patients [3, 11, 26, 27]. Historically, emergency surgical ligation of the ICA, to cease massive bleeding during pituitary surgery, has been required. However, this treatment was associated with an unacceptable high incidence of major clinical neurological deficit [20, 21]. Therefore, the development of endovascular treatment, combined with bypass surgery can provide dramatic changes on the aspect of control of the bleeding, embolization of carotid cavernous fistula and pseudoaneurysm, and cerebral revascularization to maintain good clinical outcomes [28-31]. In addition, the cavernous sinuses on both sides, which exist on the boundaries of the sella turcica, are vulnerable to injury during the TSS [21, 32]. The vascular complications should be discussed in each stage of the TSS (naso-sphenoidal, sphenoid-planum, dural, intrasellar, and suprasellar phase) with respect to the operative and neuroradiological aspects, identification of risk factors, management strategies for the avoidance of such serious vascular complications, and their outcomes.

2. VASCULAR ANATOMY OF THE TRANSSPHENOIDAL SURGERY

The process of the TSS was divided into five phases including naso-sphenoidal, sphenoid-planum, dural, intrasellar, and suprasellar. Vascular anatomic aspects of each stage are described.

2.1. Naso-Sphenoid Phase

Vascular injury can be frequently encountered on removal of the base of middle turbinate. The sphenopalatine arteries, branches of the internal maxillary artery, emerge through the sphenopalatine foramen (the height of lower margin of superior turbinate), run under the nasal mucosa, and supply the nasal structures, including nasal septum (anterior ~

posterior part: posterior septal nasal artery, inferior part: descending palatine artery) and middle turbinate (posterior lateral nasal artery). Posterior septal nasal artery, distributing nasal septum, has anastomoses with the posterior ethmoidal artery (PEA) [26]. Endoscopic observation sometimes reveals the pulsation of the artery. All the above mentioned arteries are important and should be kept in mind not to be injured. Careful attention should be paid at the procedure for dissection of mucosa at the nasal septum from the anterior wall of the sphenoid sinus. The sphenopalatine artery can be caught at the sphenopalatine foramen, through which the artery emerges, so as not to cause massive bleeding when removal of the anterior wall of the sphenoid sinus is widely required (Figure 1A) [34]. Law reported that the bleeding from the sphenopalatine artery could occur from the bone directly, from the venous diploic space or from the blood supply to stout bony structure, particularly in patients with acromegaly [20]. If the bleeding from the sphenopalatine artery is difficult to control, endovascular management, coil embolization of the maxillary artery, can be indicated. Although the midline approach would not disturb the main trunks of the sphenopalatine arteries, hemostasis of the posterior attachment of the middle turbinate, containing a branch of the sphenopalatine artery, is achieved with a suction electrocautery [34]. However, when nasoseptal pedicled flap, which is used for reconstruction of the skull base, should be made intraoperatively from the nasal septal mucosa, it is important to keep the sphenopalatine artery intact within the nasoseptal flap, whose base is required to be narrow in order to be adhered to the skull base. Therefore, the sphenopalatine artery should be stored within the narrow base of the pedicled flap [35].

Maxillary artery is the largest terminal branch of the ECA. It arises at the level of the neck of the condylar process and passes medial to it. Then, it ascends to the posterior part of the pterygopalatine fossa, and sphenopalatine artery is divided from it and run into the sphenopalatine foramen (Figure 1B). When exploring tumors, extending into the pterygoid fossa such as pituitary adenoma, adenocystic carcinoma and neurinoma, the course of the maxillary artery, which is buried in the adipose tissue at the pterygoid fossa, needs to be recognized in order to avoid an injury. Therefore, preoperative evaluation of the maxillary artery, such as 3D-CTA, is important.

2.2. Spheno-Planum Phase

Vascular injury can be frequently encountered on removal of the planum sphenoidale and the posterior base of superior turbinate, especially in the case of extended TSS for the suprasellar lesion, an unusual TSS targeting for the pituitary adenoma. PEA, which has a smaller diameter than the anterior ethmoidal artery, diverges from the ophthalmic artery and passes between the medial rectal muscle and the superior oblique muscle. Afterwards, it runs through a thin, bony channel at the medial wall of the orbit along the ethmoidal roof, seen after submucosal dissection in the posterior ethmoidal sinus [12, 33].

Although the distribution of PEA has been reported to be variable, mainly it perfuses into the superior turbinate, the posterior ethmoid sinus, the posterior part of the lamina cribrosa, and the planum sphenoidale [33]. Neurosurgeons can find the unexpected hemorrhage from PEA, if the dissection around the superior turbinate and the posterior ethmoidal sinus is carried out [11]. Although the injury of PEA is considered as an extremely rare complication

during TSS, the pituitary neurosurgeon should always have in mind the possibility of PEA injury.

In order to expose suprasellar lesions in the extended TSS approach, the superior and/or supreme turbinates should be removed along their base, taking care not to damage the turbinate lamina. During such maneuvers, it is important to avoid damaging the PEA, which frequently arises from the first segment of the ophthalmic artery and passes medially from the dura of the planum sphenoidale, to the posterior lamina cribrosa and then to the posterior ethmoidal cells [12]. Cavallo et al. reported that wide sphenoidectomy and bilateral posterior ethmoidectomy, to obtain a wider view of the planum sphenoidale, enable surgeons to clearly identify both PEAs, which are considered as “dangerous” landmarks and represent the anterior limit when opening the planum sphenoidale [10, 36]. Because the PEA branches the proximal portion of the ophthalmic artery with high blood pressure, injury of the PEA can cause massive and severe bleeding that should be avoided as much as possible.

As the PEA is a large branch stemming from the ophthalmic artery, it can be detected at the planum sphenoidale or posterior ethmoidal sinus on preoperative examinations, such as CTA. If this is the case performing the extended TSS, more attention should be paid in order to avoid unexpected severe arterial bleeding during submucosal dissection of the superior and lateral nasal cavity.

Figure 1. |A. Intraoperative endoscopic view shows the bleeding from the branch of sphenopalatine artery (posterior lateral nasal artery; A, arrow) B. is successfully coagulated with single-shaft bipolar coagulator (B, arrow) C. Intraoperative endoscopic view shows the maxillary artery (arrows) running in the pterygopalatine fossa after removal of the posterior wall of the maxillary sinus D. Hemoclips (arrows) were applied to resect the maxillary artery in the pterygopalatine fossa.

Figure 2. A. Magnetic resonance imaging of pituitary adenoma extending into the suprasellar region and compressing the optic nerves, with further invasion into the right cavernous sinus B. Intraoperatively, a massive hemorrhage suddenly appeared during mucosa dissection just above the sellar floor, suggesting the posterior ethmoidal artery (PEA) as the origin of the bleeding (white arrow) C. Digital subtraction angiography performed after the operation showed left PEA (arrow) to be responsible for this hemorrhage.

3. ILLUSTRATIVE CASE 1

A 69-year-old man presented with a 6-month history of activity loss and visual field disturbance. MRI identified a pituitary tumor extending into the suprasellar region, compressing the optic nerves and invading the right cavernous sinus (Figure 2A). Neuro-ophthalmological investigation showed bitemporal hemianopsia, and endocrinological evaluation showed a decline of adrenocorticotrophic hormone (ACTH).

During the routine endoscopic TSS, a massive hemorrhage was suddenly encountered in the sphenoidal phase during mucosa dissection just above the sellar floor (Figure 2B). It was difficult to control this arterial bleeding, and the massive hemorrhage obstructed our endoscopic view, with the total amount of blood rising up to 2280ml. The bleeding point was found to originate from the left PEA was captured under the direct endoscopic view and was controlled with the single shaft bipolar coagulator (Karl Storz Endoscopy, Tuttlingen, Germany). Partial resection of the hard adenoma was performed, and the visual field defect and decline of ACTH level were restored. DSA performed after the operation showed left PEA, stemming from the ipsilateral ophthalmic artery, to be responsible for this hemorrhage (Figure 2C). Postoperative course was uneventful, and the residual tumor has been unchanged for four years.

3.1. Dural Phase

Vascular injury can be frequently encountered on opening of the dura mater of sellar floor, especially in the case of extended TSS for a suprasellar lesion, such as craniopharyngioma. Pituitary adenomas, further manifest with ballooning of the sellar floor, and compression of the intercavernous sinus for a long period and thus leading even to its complete occlusion.

The cavernous sinuses on either side of the sella are vascular structures filled with venous blood under venous pressure. The two cavernous sinuses frequently connect through dural channels, most commonly superior and inferior intercavernous sinus. These connecting channels can be injured during the opening of the dura mater. The dura itself consists of two layers, and between them, vascular channels commonly proliferate and are diminished by compression of macroadenoma for a long period. In particular, superior intercavernous sinus usually locates between the sellar floor and the tuberculum sellae (tuberculum recessus), and coagulation and cut off of the superior intercavernous sinus is required, to advance into the suprasellar lesion during the extended TSS (trans-tuberculum sellae approach). The size and location of the superior intercavernous sinus can also influence the bone removal of the tuberculum sellae [20]. If bleeding once occurs in the cutting of the sinus, the surgical procedure will be slow and more difficult. Therefore, the incisions are made in the dura mater anteriorly and inferiorly to the superior intercavernous sinus, and the sinus is coagulated and then divided to obtain a direct view of the suprasellar cistern without disturbance by the pituitary gland [37]. In order to coagulate this sinus, the low-profile, single shaft bipolar coagulator is very useful (Figure 3).

The capsular artery, which feeds the capsule (dura mater) of the pituitary, usually is clinically insignificant and arises from the distal and medial portion of the cavernous ICA, commonly supply the sellar dura, and can also proliferate to feed any possible pituitary lesion [20, 21]. These vessels have anastomosis with the contralateral ones at the midline, and have the potential of causing technical difficulty, when dealing with the lesion directly. Zada et al. reported the midline dural filum at the sellar floor, in half of the cases examined. This filum is identified as a strand-like dural extension or as a small vascular dural structure [38]. From our intraoperative observation, active bleeding was identified from the dural filum in many of the cases, which was thought as a result of the blood supply from the anastomosis of the capsular arteries (Figure 4).

Figure 3. A. Bleeding from the superior intercavernous sinus is detected when cutting with a micro-knife and B. Coagulating with the single-shaft bipolar coagulator, in order to obtain a direct view of the suprasellar cistern without disturbing the pituitary gland.

Figure 4. A. Intraoperative endoscopic observation identifies the dural filum and the bleeding from it (arrow), which was thought to originate from the capsular arteries B. A scheme of the arterial supply over the dura mater of the sella.

Figure 5. A. 3D-CT reconstruction of oblique-coronal image (sections perpendicular to the line, from lower margin of the nostril to the top of the posterior clinoid process) as “transsphenoidal view”, is obtained as a routine preoperative evaluation of the transsphenoidal surgery for the pituitary tumors B. Intraoperative endoscopic view for the sellar floor and its surroundings after wide sphenoidectomy.

The carotid artery frequently produces a bony prominence into the sphenoid sinus wall, below the floor and along the anterior margin of the sella bilaterally (carotid prominence). Moreover, usually the optic canals protrude into the superolateral portion of the sinus, and the carotid prominence, a diverticulum of the sinus, often projects laterally between the optic canal and the carotid prominence. The dura mater over the medial surface of the cavernous sinus is exposed after removing the mucosa and bone at the lateral wall of the sphenoid sinus. Subsequently, the cavernous ICA is exposed after dural opening of the sella. Rhoton reported that there is an area between optic nerves and carotid arteries where bone thickness less than 0.5 mm from the mucosa of the sphenoid sinus in some of the cases, and meanwhile, no bony thickness is found between these structures in a few cases. The absence of such bony protection over the wall of the cavernous sinus may lead to a serious injury of the cranial nerves and the ICA during the TSS. The bone of the calvaria is often thinner over the carotid arteries than over the anterior margin of the pituitary gland [39]. Pituitary neurosurgeons are required to recognize these bony structures, related to the ICA, in order to avoid unnecessary ICA injury. 3D-CTA with thin slices of bone images is useful as a preoperative evaluation. In

our institute, oblique-coronal image (sections perpendicular to the line from lower margin of the nostril to the top of the posterior clinoid process) as “transsphenoidal view” is taken routinely in the preoperative evaluation of the TSS (Figure 5).

During the TSS approach to the sella, complete midline orientation should be maintained all the time to avoid the injury of the ICAs. Besides, the cavernous portion of the ICA is vulnerable to damage during the exposure of the sella. In the dural phase, in most cases, the injury of ICA can be encountered with the dural opening of the sellar floor. Therefore, careful preoperative evaluation of bony structure in the sphenoid sinus as well as measurement of intercarotid distance is essential to avoid the serious ICA injury [20]. Perdoni et al. reported that the mean intercarotid distances found at the level of tuberculum sellae, sellar floor and clivus were 13.32, 18.00 and 18.90 mm respectively. The distance between ICAs at the tuberculum sellae is narrower than that at the sellar floor. The mean distance found between the ICAs at the level of the 18 mm sellar floor can be considered a “safe zone” to access the hypophysis, and other researchers reported similar value [40]. However, endoscopy is very useful in providing a panoramic view of the depth in the sphenoid sinus, including bilateral carotid prominence and opticocarotid recessus. Fujii et al. reported an interesting study, showing the various parts regarding bony thickness of the posterior wall of the sphenoid sinus. In this chapter, the thickness of the bone of the sphenoid sinus together with the intracranial ICAs was described as follows; the thickness of the bone separated the ICA and sinus is less than 0.5 mm in 88% of cases, and areas of bone defect were present in 8% of them [41]. Therefore, fine maneuvers are required and easy cautery should be avoided as much as possible. In this connection, the vidian canal can be a critical landmark for the petrous and parasellar ICA [12]. Identification of this landmark and the parasellar and paraclival carotid prominence is also critical in staying oriented to the petrous ICA [42]. The bone over these prominences can be carefully and safely removed to have the ICA in view [43].

4. ILLUSTRATIVE CASE 2

A 38-year-old man presented with activity loss and visual field deficits that had been ongoing for the last two months. He had consulted previously another clinic, where a large-sized suprasellar extended tumor was detected with MRI, and was referred to our department where neurological evaluation revealed bitemporal hemianopsia, and endocrinological evaluation showed reduced levels of baseline cortisol, ACTH, and thyroid hormones. MRI showed a calcified solid mass with remarkable suprasellar extension compressing both optic nerves upward (Figure 6A). Extended endoscopic endonasal TSS was performed, and gross total removal of the tumor was achieved and subsequently visual function was remarkably improved. Pathological diagnosis of the surgical specimen was non-functioning pituitary adenoma.

Intraoperatively, during right-sided dissection of the dural phase of the TSS, arterial bleeding emerged from the right ICA, during the removal of the bone at the carotid prominence (Figure 6B). Hemostasis was immediately carried out with continuous aspiration of the hemorrhage without leading to catastrophic hemorrhage. Tumor was successfully removed via extended TSS, and the patient was discharged without any neurological deficit.

Figure 6. A. Magnetic resonance imaging (MRI) reveals the non-functioning pituitary adenoma extending into the suprasellar cistern B. During right-sided dissection of the dural phase of the transsphenoidal surgery, arterial bleeding emerged from the small branch of the right ICA (arrow) during the removal of the bone at the carotid prominence C. MRI obtained one month later revealed de novo flow void mass with anterior protrusion at the right cavernous ICA D. DSA demonstrated aneurysm formation at the right cavernous ICA, suggesting pseudoaneurysm E. Endovascular embolization of parent ICA to occlude pseudoaneurysm and superficial temporal artery-middle cerebral artery anastomosis for cerebral revascularization was successfully performed. Postoperative DSA revealed disappearance of the aneurysm and F. excellent restoration of the blood supply from the ECA to the ICA.

However, one month later, follow-up MRI revealed de novo flow void mass at the cavernous ICA (Figure 6C). DSA was performed to demonstrate aneurysm formation at the right cavernous ICA, and it was most suspected to be pseudoaneurysm (Figure 6D). The risk of aneurysm rupture is considered to be quite high. Therefore, in order to prevent rupture the aneurysm, endovascular embolization of parent ICA to occlude pseudoaneurysm and superficial temporal artery-middle cerebral artery anastomosis for cerebral revascularization was successfully performed. Postoperative DSA revealed disappearance of aneurysm and

restoration of the blood supply from the ECA to the ICA (Figure 6E, 6F). Cerebral blood flow measurement showed no perfusion defect and MRI showed no ischemic changes on the right hemisphere. The patient left the hospital with no neurological deficit. In a later time-point, residual tumor was managed with conservative treatment.

4.1. Intrasellar Phase

Vascular injury of ICA and its perforator can be encountered on removal of tumor invading into the cavernous sinus or incision of cavernous sinus wall. The ICA sometimes can be tortuous and protrude to the midline [32]. Therefore, ICA injury in this phase frequently leads to the fatal neurological and systemic complications, with published rates, occurring by the use of traditional open approaches ranging from 3% to 8%. [44, 45], whereas for standard microscopic TSS for pituitary tumors ranging from 0.2% to 1.4% [5, 18, 20]. On the other hand, cases in which endoscopic endonasal surgery was used, a limited number of ICA injuries were reported, suggesting that these were indeed rare [37, 46, 47]. Moreover, increased use of the endoscopic endonasal approach for skull base lesions can provide wide exposure and visualization of its surroundings with remarkable advancement of the specialized instrumentation [8, 9]. It can allow improved localization and control of the ICAs. However, increased chances of dissection due to endoscopic wide visualization around the ICAs may result in a higher rate of ICA injury [26]. In some cases, the parasellar ICA protrudes inside the adenoma with remarkably tortuosity. Cautious preoperative evaluation is required to prevent fatal ICA injury and remove the tumor efficiently (Figure 7).

Because little or no separation exists between the medial portion of the ICA and the lateral surface of the pituitary gland, blunt instrument should be used for the dissection of the tumor periphery inside the sella. Perforation or laceration of the ICAs in the cavernous sinus represents a very serious problem and unfortunately is a common type of injury in the TSS [21]. In the cases of large invasive pituitary adenomas eroding the skull base, tumors may actually surround the ICAs and, occasionally, may invade the adventitial wall of the vessels, which causes injury to the integrity of the ICAs, when the tumor is removed radically. Dissection of tumors away from the ICAs or displacement of the ICAs in the cavernous sinus during an attempt to achieve hemostasis can lead to thrombosis of the ICAs, resulting in occlusion and occasionally embolization.

Important branches of the ICA, supplying the pituitary gland with blood, arise from the meningohypophyseal trunk, which arises between the carotid segment C4 and C5 and supplies the pituitary gland and the pituitary stalk [20]. This trunk can also proliferate to provide blood supply to pituitary tumors. It divides into three branches, inferior hypophyseal branch, dorsal meningeal branch, and tentorial branch. Inferior hypophyseal branch is the largest of these three, and runs medially to supply the posterior pituitary lobe, appearing as the latter's net of terminal vessels [12, 44].

Direct injury to the carotid artery frequently leads to formation of a pseudoaneurysm, like in our case described above, even if the artery appears to be intact up to the point of maintaining its flow inside the ICAs without further bleeding. According to some authors' reports, the rates of pseudoaneurysm formation after ICA injury are generally very high, and carotid cavernous fistula and thrombosis can occur either [26, 48]. Kai et al. reported a case of a patient who suffered a pseudo ICA aneurysm following TSS, and cerebral angiograms

showed a pseudoaneurysm arising from the C4 portion of the left ICA. It was successfully treated with bypass surgery and ICA occlusion involving the pseudoaneurysm using coil embolization. Postoperative angiograms showed that the pseudoaneurysm was completely occluded and the bypass was fully patent. Authors addressed that massive arterial bleeding is encountered during TSS, therefore the patient should be carefully monitored to detect early the development of a pseudoaneurysm. When such an aneurysm is found to have ruptured, interventional surgery has proved effective in the management of this complication [49].

Figure 7. In a representative case was shown the ICA protrusion into pituitary adenoma, the latter invading into the cavernous sinus. A. Preoperative MRI revealed that the cavernous ICA was involved in the adenoma. An intratumoral cyst was identified B. Preoperative CTA revealed tortuous cavernous ICA protruding into the adenoma C. Intraoperative endoscopic view after opening of the intratumoral cyst clearly showing the tortuous ICA to be adjacent to the cyst.

The ICA can be placed into mechanical spasm by causing dissection around the ICAs or injury to them. TSS complicated by peritumoral hemorrhage is associated with a significant rate of neurological deterioration, due to delayed cerebral vasospasm, and this spasm can clearly cause arterial insufficiency and stroke [26]. Therefore, early recognition and proper management, according to guidelines used for postaneurysmal subarachnoid hemorrhage (SAH), may help to prevent deterioration of outcomes in those patients [19, 50]. Puri et al. reported three cases of developed vasospasm of the intracranial vessels after TSS, with extension of peritumoral hemorrhage into the subarachnoid space, starting as early as postoperative day 5 and continued as late as postoperative day 10. The outcomes of these three cases were not excellent; therefore, they concluded that the vasospasm after TSS associates with the significant risk of neurological morbidity [50]. The timing and distribution of cerebral vasospasm after TSS is similar to that observed in the patients after SAH due to aneurysmal rupture. Therefore, the management of the vasospasm including early vascular imaging evaluation, aggressive hyperdynamic therapy, and neurointerventional procedures should be applied to prevent upcoming ischemic complications [50-52].

4.2. Suprasellar Phase

Pituitary adenoma with remarkable suprasellar extension, in particular, in the case with significant anterior skull base extension, the extended transtuberulum sellae-transplanum sphenoidale approach is required to remove the pituitary adenoma. With this approach, the suprasellar cistern is fully exposed during and after the surgery [53, 54]. Vascular injury, at the level of supraclinoid ICAs and their branches, can be encountered on dissection between the tumor and the vessels involved or adhered to the tumors at the suprasellar, the interpeduncular, and the prepontine cisterns. Thus, ICA, superior hypophyseal artery, anterior and posterior communicating arteries, posterior cerebral artery, basilar artery and its perforators, and superior cerebellar artery, are the vessels affected during the extended endoscopic TSS (Figure 8). Therefore, during the manipulation of the vessels in the suprasellar phase, neurosurgeons should take into consideration the anatomy of the Circle of Willis and its integrity with respect to its collateral flow [48]. Concerning their branches and perforators, special attention should be paid to the injuries of the hypothalamic arteries, but also prevention of a direct hypothalamic trauma, which could cause recent memory disturbance [25]. Once the pituitary stalk can be seen in the subchiasmal spaces, the superior hypophyseal artery and the perforating branches for the inferior surface of the chiasm are apparent, and the posterior communicating artery and its perforator are also detected in the deeper parts of the operative field [10]. During the removal and dissection of the tumors at the TSS, the vascular anatomy around the suprasellar cistern turns to be very complex and is frequently distorted in the cases of large tumors. Besides, above the diaphragm sellae, a circuminfundibular venous plexus exists and can elaborate to feed pituitary lesions. As mentioned above, more expanded approach to obtain wide operative field and excellent visualization, with greater ICAs manipulations and subsequent ICAs' exposure, could increase the risk of vascular injuries [12, 27]. However, in some series, it was indicated that lateral exposure of pituitary tumors enable wider range of endoscope access than microscope and does not lead to a remarkable incidence of injuries overall of for tumors. In the cases of vascular injuries described above, massive bleedings flow into the sphenoid sinus and nasal cavity. However, in this phase, massive bleeding due to the vascular injuries "attacks" hypothalamus, intraventricle and brainstem, causing fatal neurological deteriorations. Besides, once the vascular injury occurs, it is very difficult to control the bleeding, so as to maintain visualization at the deep and narrow operative field, thus higher techniques are required to find the bleeding point [27].

Needless to say, the best strategy for managing ICA injuries during the TSS is prevention. Therefore, considerable preoperative neuroradiological assessment of the course of the ICAs at the suprasellar cistern is essential, as well as tumor and patient risk factors (e.g., ICA involvement with tumor, atherosclerosis in patients with acromegaly or Cushing disease) [27].

When exploring a suprasellar lesion below the optic chiasm such as craniopharyngioma, preservation of chiasm vascularization, fed from the superior hypophyseal artery is partially important, and extended transsphenoidal approach with endoscope offers an excellent visualization, in order to avoid any vascular injury resulting during the dissection between the tumor and the vessels [11]. An avulsion of perforator arising from the P1 portion of posterior cerebral artery during the resection of the part of suprasellar extension of pituitary adenoma

may occur, and Kassam et al. used a topical hemostatic agent to control the bleeding, but as a result of this forcible tearing, the patient suffered from severe transient dysphagia [36].

Figure 8. A. Intraoperative endoscopic view clearly revealed the anterior communicating artery (white arrows) and anterior cerebral arteries (black arrows) and B. the ICA (white arrows) and the superior hypophyseal artery (black arrows) after removal of pituitary adenoma via the extended trans-tuberculum sellae approach.

5. PROCEDURES AND INSTRUMENTATIONS FOR THE PREVENTION AND CONTROL OF BLEEDING

As mentioned above, the first problem related to this approach concerns the control and prevention of bleeding, especially in the procedures of intra- and supra-sellar phases. Because it is difficult to control massive bleeding coming from the main vessels, as many neurosurgeons addressed, it is important to make all surgical maneuvers under the direct endoscopic view [16].

In particular, in the suprasellar phase, angled 30° or 45° 4 mm rigid endoscope was used to assess the completeness of tumor removal and to help observe the tumor-neurovascular interface clearly [1, 9, 37]. Dusick et al. reported that the use of the micro-Doppler probe for carotid localization before dural opening and angled hook blades for lateral dural opening are potentially simple and effective surgical adjuncts that can help minimize the risk of ICA injury, and recommended for all TSS as routine intraoperative examination (Figure 9)[19, 22]. Kitano and Taneda reported the use of the micro-Doppler probe later during tumor resection within the cavernous sinus, in order to confirm the ICA course, as a technique that they strongly recommended [55]. In addition, the Doppler is more reliable than neuronavigation systems, because it gives real time feedback, whereas the latter are prone to varying degrees of inaccuracy even for fixed cranial-base landmark [2, 56]. Indocyanine green fluorescence shows promise as an intraoperative marker in differentiating pituitary tumors from normal gland, and virtually identifying areas of dural invasion without development of any adverse events [57]. Yano et al. clearly demonstrated intraoperative visualization of the intercavernous sinus before dural incision and the cavernous ICA in the intrasellar phase, and encouraged the improvement of the tumor resection with more safety and effectiveness [35]. Although the indocyanine green fluorescence has not yet become popular in the TSS, these results support the further development of fluorescence-guided tumor resection techniques, since these can lead to improved outcomes, from the aspect of

preservation of normal gland, extent of tumor resection, and avoidance of vascular injury. Dusick et al. also addressed that the use of low-profile hook blades for dural opening can reduce the risk of the ICA and other vascular injuries because the blade angle allows the cutting force to be directed away from the intradural surface and back toward the surgeon instead [19]. Rhoton proposed that angled piston-gripped dural scissors could be used for this purpose [58].

Figure 9. Micro-Doppler probe (black arrow) for localizing carotid artery (white arrow) during the removal of pituitary adenoma, to prevent the ICA injury. The procedure is recommended for every kind of transsphenoidal surgery as routine intraoperative examination.

Figure 10. Low-profile bipolar coagulator for the coagulation of vessels of the tumor capsule, making possible the bipolar coagulation of arterial bleeding in narrow spaces.

Low-profile bipolar coagulator, specially designed to work through the nose, with tips up to 0.3 mm and single shaft, are now available for the coagulation of vessels of the tumor capsule, making possible the bipolar coagulation of arterial bleeding in narrow spaces (Figure 10). Vascular clips with an applicator designed for endonasal use can be useful for the bleeding control of the vascular injuries in the naso-sphenoid and sphenoid-planum phase

[20]. However, these devices are not practical for the ICA injury for the fear of enlarging the hemorrhage point.

Although the bleeding due to the ICA injury during the TSS is so massive and difficult to control in the operative field, most ICA injuries originated from small puncture wounds that can be fortunately controlled in an initial phase with Gelform and cottonoids. Therefore, when the neurosurgeons encounter the ICA injury during the TSS, they must detect the accurate bleeding point of the ICA injury despite of the difficulty in controlling a massive bleeding at first moment [30]. Following the initial care, the next steps include a two-layered muslin gauze patch or collagen sponge immersed in fibrin glue or BioGlue, and then a fat graft put over the puncture point accurately. Harvested fascia with fibrin glue is strong and adhesive material, which can be applied to the puncture point for the control of the bleeding [59]. But neurosurgeons need to prepare the fascia and fat graft from abdomen or thigh in advance intraoperatively. However, overpacking the repair of injured site should be refrained, because it could result in carotid occlusion and subsequent cerebral infarction. The use of the clip to control the bleeding and preservation of the vessel patency is reported in some cases [20]. Direct suturing repair for the larger laceration of the vessel is basically not practical, because suturing technique is quite difficult and time consuming at that serious situation.

Unfortunately, if the arterial bleeding from the injured vessels is not controlled finally, trapping of the vessels with aneurysm clip is applied to the injured site or the parent artery, thus “sacrificing” the vessels. However, recent advancement of endovascular surgery has changed the methods to repair the vascular injuries [28]. As some authors have already described and vascular group of our institute performs, urgent cerebral angiography should be carried out in the operating room. After the detection of the extravasation and presentation of a pseudoaneurysm or carotid cavernous fistula, balloon is approached to the injured site and inflated to occlude the parent vessels [28, 29, 48]. After the repair of the injured site, ICAs are supposed to be involved in most of the cases, it is needed to confirm that the injured site is successfully repaired after deflation of the balloon and collateral circulation via the Circle of Willis in the case of ICA occlusion should be assessed [30]. With the appearance of pseudoaneurysm or carotid cavernous fistula, endovascular treatment, involving ICA embolization, should be immediately achieved [31, 60, 61]. In this case, since the collateral circulation is not excellent via anterior communicating artery or posterior communicating artery, the ECA-ICA bypass surgery, including superficial temporal artery-middle cerebral artery anastomosis, high flow bypass using arterial graft, should be immediately performed to prevent the subsequent ischemic complication due to the ICA embolization [49]. Even if the result of the angiography is normal after the vascular injury, it is strongly recommended to repeat DSA or 3D-CTA within five days to detect the delayed occurrence of any possible pseudoaneurysm. MRI should be also carried out and evaluated, whether cerebral infarction emerges in the case of the ICA embolization, and CT scan should be also obtained immediately after endovascular procedure, whether SAH occurred, which can lead to clinically significant cerebral vasospasm [50, 62].

Chapter 375

TRANSSPHENOIDAL SURGERY FOR PITUITARY ADENOMAS GUIDED BY INTRAOPERATIVE MAGNETIC RESONANCE IMAGING (iMRI)

Sven Berkmann*, MD and Javier Fandino, MD

Department of Neurosurgery, Kantonsspital Aarau, Tellstrasse, Aarau/Switzerland

ABSTRACT

Transsphenoidal surgery is the first-line treatment in the majority of symptomatic sellar tumors. The goals are cure of endocrinological syndromes (e.g., acromegaly), neurological deficits (e.g., optic chiasm compression syndrome), restoration of pituitary function and long-term tumor control. With the evolution of the transsphenoidal approach, several tools like the X-ray intensifier, cisternography, sonography, computed tomography, the endoscope, and the intraoperative MRI (iMRI) have been used to increase visualization of the tumor and thereby to make surgery safer and to increase the extent of resection.

The iMRI has been used since 20 years in combination with a microscopic or endoscopic approach and numerous studies have shown the efficacy of iMRI-controlled transsphenoidal surgery, as well as identified the indications and drawbacks of the various setups and subtypes. Based on our own peer-reviewed clinical studies and by reviewing the literature we will present critical insights in the use of this fascinating technology for transsphenoidal pituitary adenoma surgery.

Keywords: pituitary adenoma, transsphenoidal surgery, intraoperative MRI

1. INTRODUCTION

Transsphenoidal surgery is the first-line treatment in the majority of symptomatic sellar tumors. The goals are cure of endocrinological syndromes (e.g., acromegaly), relief of neurological deficits (e.g., optic chiasm compression syndrome), restoration of pituitary

* Corresponding Author's Email: sven.berkmann@ksa.ch.

function and long-term remission. Nevertheless, due to the narrow access to the *sella turcica* and its adjacent compartments, the rate of unsuspected – and further resectable - tumor remnants after surgery may be high. While gross total resection (GTR) of hormonally active pituitary adenomas is mandatory for cure of endocrinological syndromes, most remnants of hormonally inactive tumors may regrow within 5 years after resection and eventually cause local compression symptoms again [1]. Nevertheless, aggressive probing for tumor remnants may lead to severe complications due to the proximity of the optic nerves, the internal carotid arteries and the cavernous sinus. Visualization of the tumor and safe exploration of the surgical site is therefore the key to successful transsphenoidal surgery.

Lars Leksell advocated the philosophy that no technique in neurosurgery could be too refined, particularly in reference to the ability to localize lesions [2]. This is especially true for pituitary surgery. The first transsphenoidal tumor resection was performed by Hermann Schloffer (1886-1937) on March 16th 1907 in Innsbruck, Austria [3]. After a number of modifications culminating in the description of the oronasal rhinoseptal approach with a sublabial gingival incision by Albert Edward Halstead (1869-1926), Harvey Cushing (1869-1939) adopted this technique and performed 231 such procedures from 1910 to 1925. Ultimately Cushing abandoned the transsphenoidal approach. He reverted to the transcranial technique because he believed that the optical structures may thereby be more readily decompressed. Ultimately, this was a direct consequence of the non-existing possibility to sufficiently visualize the surgical site by the transsphenoidal approach. Due to Cushing's influence at the time, many surgeons followed his example. The transsphenoidal approach to the pituitary was mostly neglected for 40 years and it was only in the middle of the 60s with the birth of micro-neurosurgery and the introduction of the operating microscope when the renaissance of the transsphenoidal approach began.

Various tools for a better visualization of the tumor and its adjacent structures and for tailoring the transsphenoidal approach have been introduced during the subsequent 50 years. Principally, the further evolution of pituitary surgery was paralleled by the improvement of intraoperative imaging [4, 5]. In 1965 Hardy introduced the use of radiofluoroscopy in combination with the operating microscope [6]. Nevertheless, as the X-ray intensifier only allowed depiction of the skull base and the metal instruments introduced, there were further attempts in conjunction with cisternography to assess the suprasellar extension of the tumor [7]. In 1993 intraoperative computerized tomography was proposed as a more progressive tool to appraise the extent of tumor resection. At this time it was suggested that intraoperative CT scanning would probably remain the preeminent modality for conventional intraoperative image-guided surgery because of the enhanced access to the operating field and its instrument compatibility as compared to the iMRI, which almost evolved at the same time [8]. Nevertheless, use of radiation, fixed slice orientation, and especially the poor soft-tissue contrast limited the benefit [9]. Other attempts [10-12] to further localize the surrounding anatomical structures included ultrasonography and the color Doppler system; however, none of these tools reached a high level of acceptance as an independent method to assess the extent of resection [13-15].

During the past 15 years the evolution of image-guided neuronavigation based on preoperative datasets referenced to the patient's head began to replace intraoperative fluoroscopy for orientation in the surgical site more and more [16-21]. Because one of the main reasons for incomplete tumor resection is poor exposure of the sellar space, neuronavigation facilitated the optimal tailoring of the approach. In conjunction with

intraoperative imaging, real-time assessment of the grade of resection became possible because the neuronavigation datasets could be immediately updated with the new footage.

The intraoperative MRI (iMRI) has been used since 1994 [22]. In the subsequent years a growing number of departments all over the world adapted MRI systems to their operating theaters. In transsphenoidal surgery it allows a quick evaluation of the extent of tumor resection, an update of images for intraoperative navigation, and the exclusion of imminent complications (e.g., hemorrhage or ischemia), before the site is closed. Numerous studies have shown the efficacy of iMRI-controlled transsphenoidal surgery, as well as identified indications and drawbacks. In the first part of this chapter an overview of the different setups and subtypes of iMRI with respect to their pros and cons will be given. In the second part, today's experience in iMRI-controlled transsphenoidal surgery for pituitary adenomas with respect to the different pathological entities will be reviewed, before a critical review of the arguments in favor of and against the use of iMRI is finally given.

2. TECHNICAL SYSTEMS AND OPERATING ROOM SETUPS

The basic problems to be solved when using an iMRI are the following:

1. Electromagnetic interaction and compatibility of electrical devices used by the surgeon and the anesthesiologist
2. Ferromagnetic interaction between the surgical instruments and the scanner, which may not only influence image quality, but also the microsurgical handling of the devices and the safety of the patient and the operation personnel
3. Electromagnetic shielding to avoid loss of image quality caused by exogenous fields
4. Access to the operating field and possibilities for patient positioning. All these problems are directly correlated with the field-strength of the MR-scanner.

Therefore, two basic concepts for the use of iMRI have evolved: operating within the magnet and its associated field or moving the patient to the magnet only for scanning (i.e., “two room concept”). Commonly, the setups which make it possible to operate within the field are using field strengths up to 0.5 Tesla (T). These so-called ‘low-field setups’ are markedly different from ‘high-field setups’, which use magnetic fields from 1.5 to 3 T.

The first truly incorporated MR scanner within an operating room was the Magnetic Resonance Therapy Unit at Brigham and Women's Hospital in Boston, Massachusetts, introduced in 1994 [22]. It was a collaborative project between Peter Black as Head of the Neurosurgical Department, Marvin Fried, Director of the Department of Otorhinolaryngology, and Ferenc Jolesz of the Department of Radiology, and engineers at General Electric Medical Systems (Milwaukee, Wisconsin). In the late 1980s, the closed-configuration of conventional MRI systems prohibited access to the patient; therefore, fundamental changes in magnet and coil design and display methods were necessary. This resulted in a “double donut”-shaped scanner, with a magnetic field of 0.5 T in the space between the two “donut” rings (GE 0.5-T Signa SP). The surgeon was standing in the limited space between the two superconductive magnet coils. Along with the design of the iMRI, many commonly used tools had to be adapted: ferromagnetic surgical instruments were

replaced by titanium; the Mayfield head holder device was remodeled from high performance plastic; the power-drill used for e.g., modeling the craniotomy flap was redesigned by the Midas Rex Corporation (Medtronic, Minneapolis, Minnesota) as a non-ferromagnetic tool; the ferromagnetic joints of the operating microscope were replaced by plastic; and finally a bipolar coagulator not interfering with the magnetic field was introduced. Anesthesia and patient monitoring devices that did not emit electronic noise were at that time already in use for performing pediatric MR imaging under anesthesia and could be installed in the iMRI suite.

After the potential of the iMRI and its benefits became obvious, the next step was to optimize its availability and to develop cost-effective units. In Erlangen, Germany, Rudolf Fahlbusch, Michael Buchfelder, and Christopher Nimsky from the neurosurgical Department first developed together with their colleagues from Heidelberg and Siemens Medical (Siemens AG, Erlangen, Germany) a 0.2 T scanner (0.2-T Magnetom Open™; Siemens Medical solutions) in 1996, before moving on to a 1.5 T scanner (Magnetom Sonata Maestro Class™; Siemens Medical Solutions) in 2002. Integral to the new high-field concept was the possibility of simultaneous intraoperative imaging and neuronavigation. The setup was based on a rotatable surgical table (Trumpf, Saalfeld, Germany), which could be locked into various positions and adapted to the scanner to allow for a special surgical MR tabletop. MR-compatible monitoring was installed for control of anesthesia and for wireless 2.4 GHz data transfer from the radiofrequency-shielded cabin. For intraoperative navigation, the patient's head was fixed in a 5-pin head holder (Noras MRI products, Hoechberg, Germany) with an integrated 8-channel coil. This allowed to directly update the intraoperatively acquired datasets for neuronavigation without additional referencing. One shortcoming of this system is that patients can only be positioned in the prone or supine position. The neuronavigation datasets were used in conjunction with a navigation microscope placed inside the 0.5 mT zone. As opposed to the image quality generated by low-field-iMR systems, the quality obtained by high-field-strength scanners compared well to regular diagnostic MR-images. In addition, functional MRI, MR spectroscopy and fiber tracking became possible during surgery. For a regular T1- or T2-scan including the draping the scanning time amounts to about 10 to 15 minutes.

While various other low-field settings have been described [23, 24], one of the most widely used units are the PoleStar™ systems (Medtronic Navigation, Louisville, Colorado). This low-field setup was driven by the Israeli surgeon Moshe Hadani and his group and introduced in 2001 [25]. The initial model PoleStar™ N-10 iMRI consisted of a 0.12 T magnet that required only modest remodeling of the operating room. The actual model, PoleStar™ N20, comes with a 0.15 T-magnet (Figure 1).

The portable device is stored within a small garage next to the operating room and at need installed beneath the operating table. Thus, in contrary to a permanently installed scanner, the use of the operating theater is not dominated by the iMRI. A neuronavigation system (StealthStation TREON™, Medtronic) is integrated in the system, which detects not only the position of the patient but also of the iMR-scanner. During the scans radiofrequency shielding is maintained by a foldable tent (StarShield™, Medtronic), which encloses the magnet and the whole operating table. Although the surgical field is directly above the scanner, the use of ferromagnetic tools is still possible due to the comparably low field strength. Nevertheless, the power drill and the patient monitoring devices still have to be MR-compatible. The titanium head clamp and the space within the magnet allow prone, supine

and lateral positioning. As in the high field-setup, the scanning time including the draping amounts to about 15 minutes. One of the major drawbacks compared to the high field-iMRI is the low contrast and resolution of the images when used for pituitary surgery. The optic chiasm, the pituitary stalk and the internal carotid arteries may be readily identified, while invasive tumor in the cavernous sinus may be difficult to differentiate from the venous caverns [26, 27].

3. OUTCOME OF iMRI-CONTROLLED TRANSSPHENOIDAL SURGERY

Since 1994 a growing number of studies addressing the outcome of iMRI-controlled transsphenoidal surgery have been published [1, 26-56]. An overview of the literature is given in *Tables 1* and *2*. While earlier studies mostly aimed at feasibility and technical issues and presented patient groups with mixed pathologies [28, 46], the end points of recent studies have become more specific in reporting the outcome of the individual pituitary tumor pathologies, and in assessing the course of symptoms and the long-term outcome [1, 26, 47].

Figure 1. The PoleStar™ N20 unit with integrated neuronavigation system S7. (picture provided by courtesy of Medtronic Switzerland).

3.1. Nonfunctioning Pituitary Adenoma

Transsphenoidal surgery is the first-line treatment in symptomatic hormonally inactive pituitary tumors and histological specimens will show nonfunctioning or so-called silent secreting pituitary adenomas (NFA) in most cases. Serial imaging by MRI is mandatory as a postoperative follow-up routine, as there are no other markers (such as serum hormone levels) to hint for regrowth of tumor remnants or recurrence after GTR before local compression symptoms occur. Roelfsema et al. [57] found a recurrence rate for NFA after transsphenoidal surgery of 0.022 patients/year by analyzing 31 studies. Kaplan-Meier analyses show relapse rates of 23, 47 and 68% at 5, 10 and 15 years, respectively [58].

Therefore, GTR is the highest goal of surgery for NFA. Nevertheless, due to invasive or expansive tumor growth or lack of intraoperative visualization of unsuspected remnants, the final GTR rate may not be as high as could be preoperatively expected. The main reason for a reoperation in these patients is regrowth of tumor remnants [56, 58]. While residual tumors may shrink spontaneously during the first months after surgery, virtually all of the visible remnants do grow during long-term follow-up [1, 59]. The majority of regrowths is detected within 5 years after surgery; however, compared to hormonally active adenomas, up to 50% of these tumors may recur later [1, 57]. Because of invasive growth into the cavernous sinus or the clivus and because of abundant supra- and retrosellar tumor masses surgical resection is sometimes intended to remain incomplete; however if a complete resection seems possible, it is very unfortunate for the patient if tumor is left behind due to limited visualization during surgery. Consequently, this may provoke the discussion whether to re-operate in a patient who has possibly become asymptomatic, or whether to embark for lifelong high-frequency screening for regrowth.

This is the place for using the iMRI in NFA because, as will be shown, it significantly reduces the rate of unexpected remnants. While there was a tendency in the earlier phase to treat as many patients as possible with iMRI-control to gather further experience, latter studies are based on the thereby evolved indications for its use. These criteria include e.g., invasive tumor growth, history of previous transsphenoidal surgery and awkwardly irregular (e.g., dumbbell) shaped tumors. A selection for the use of iMRI in pituitary surgery is often necessary, because of the eventually high caseload of pituitary patients in large centers compared to the operating time capacity in the iMRI, which may also be used, for example, for glioma and epilepsy surgery.

Generally, acquisition of iMRI controls is decided in case GTR is supposed or if incomplete resection is suspected but no further removal seems safely possible. As with several study-designs on the use of intraoperative diagnostics, one may argue that the possibility of visualizing the tumor with iMRI may have weakened the effort to probe for occult remnants. Nevertheless, as control scans are generally time consuming and a final scan before the site is closed is mandatory, most surgeons may avoid supplementary scans. In most cases 2 to 3 scans are needed: the first scan before resection is started as a baseline benchmark for comparison, the second to look for remnants and an eventual third to ensure removal of these remnants.

The use of iMRI facilitates GTR. This is the common conclusion in studies on iMRI-controlled transsphenoidal surgery. For the pathologies operated with low-field iMRI (Table 1) the mean increase of GTR rates was 22% (range 3-52%). Additional resections based on iMR images were performed in 27-100% (mean 81%) of the patients. For high-field iMRI studies (Table 2) the mean increase of GTR was 21% (range 9-33%) and additional resections were possible in 27-100% (mean 67%) of the patients. The broad range of these results is characterized by the variability of types, sizes and grades of infiltration of pathologies included in these various studies. As mentioned above, some NFA are deemed for intended incomplete resection. The mean GTR rate in the low-field studies (Table 1) was 57% (range 17-80%) in the first intraoperative scan and 77% (38-100%) in the postoperative scan. In high-field studies, the initial mean GTR rate was 47% (range 17-89%) and 67% (38-100%) after additional resection. It is noteworthy that a meta-analysis of 5.022 patients with NFA operated without the use of iMRI reported a mean GTR rate of 44% [57]. This reflects nicely the GTR rate detected by the iMRI scans before further resections based on these images were made.

To assure a good outcome, long-term follow-up is the key in NFA; however, there are only few studies with mean follow-ups over 1 year. In a recent series on transsphenoidal surgery for NFA assisted by ultra-low-field MRI, an initial GTR rate of 85% was reported for 60 NFA with a mean volume of 6.8 cm³. No recurrences were seen during a mean follow-up of 3.2 years (0.5-4.3 years) [27]. Another study with a follow-up of 2.8 years in 104 patients with NFA, who were operated in a PoleStar™-unit, detected recurrences in 3% of the patients [44]. For high-field iMRI, the study [1], with the currently longest mean follow-up (5.6 years) reported recurrences in 7% of the patients resulting in a comparably low recurrence rate of 0.013 patients/year (as compared to the quoted meta-analysis which reported a rate of 0.022 patients/year) [57]. In the same study, regrowth of known remnants after incomplete resection was noted by follow-up imaging in 64 % of the patients. The regrowth rate was 0.114 patients/year. Seventy-nine percent of these patients showed further growth within 5 years after surgery.

In the case of recurrence of NFA after GTR or regrowth of tumor remnants, treatment options include observation, radiotherapy, stereotactic radiosurgery, and transsphenoidal reoperation or craniotomy. Transsphenoidal reoperations for tumor resection may be challenging, due to the varying operative anatomy, frequently invasive growth of these recurring tumors, loss of anatomical landmarks, the effects of radiotherapy and the presence of scarring. While various studies on the use of iMRI also included patients with reoperations in their mixed study groups, a recent study explicitly reports on this subject [56]. The initial GTR rate in these patients was 17%, which correlates well with the rates reported in the literature on transsphenoidal reoperations without iMRI [60]. Further resection based on the updated iMRI sequences was possible in 67% of these patients, resulting in a final GTR rate of 49%. In patients with noninvasive tumors the GTR rate could even be increased from 31% to 75%. Nevertheless, the GTR rate of 49% is still low compared with data from iMRI studies on first-time procedures (Tables 1 & 2). The complication rate for reoperations was reported to be significantly higher than for primary surgery [61]. Diabetes insipidus, meningitis and cerebrospinal fluid (CSF) fistulas, as a sequelae that need to be repaired, may be present in up to 25%, 5% and 9% of these patients, respectively. The reported rates for iMRI-controlled resections did not exceed the incidence reported in the literature for primary procedures [62,

63]. Persistent diabetes insipidus was found in 3%, reoperations for CSF leaks were indicated in 4% of these cases and 2% of the patients suffered from postoperative meningitis [56].

Even if not completely resectable and as stated, this may be e.g., more often the case in reoperations of recurrent tumors or in invasive tumors the iMRI may facilitate remnant volume reduction [1, 56]. This is essential if further therapy options like conventional or stereotactic irradiation have to be indicated. Tumor control rates of 90% were reported for fractionated radiotherapy [64, 65], as well as for stereotactic irradiation such as Gamma Knife radiosurgery [66-69]. The peak of tumor size reduction is seen about 3 years after radiotherapy, and volume reductions of 50% have been described within 5 years [70, 71]. Additionally, radiosurgery may be an option for local control in patients with pituitary adenomas who have already undergone radiotherapy [72]. Tumor volume is one of the most important issues for indicating radiosurgery. The main factor influencing the incidence of tumor regrowth or the induction of neurological deficits by radiosurgery is a tumor volume greater than 5 cm³ [68, 73]. Therefore, even if complete resection may not be possible, additional iMRI guided reduction may achieve smaller remnant volumes and thereby enhance the efficiency and at the same time reduce the morbidity of radiotherapy.

3.2. Outcome of Compression Syndromes

If not detected incidentally by MRI or CT imaging, indicated for non-pituitary related disorders, pituitary adenomas and typically NFA may grow extensively. With time they lead to damage of the anterior visual pathway, such as visual field (VF) defects or decline of visual acuity (VA) as described by Harvey Cushing in 1935 [74, 75]. Oculomotor and facial sensibility disturbances may be seen in the case of parasellar extension to the cavernous sinus, and even obstructive hydrocephalus may occur when the third ventricle is compressed. For ophthalmological symptoms, early decompression of the chiasm and the optic nerves significantly improves visual outcomes [76, 77]. In the case of rapid VA decline caused by pituitary tumor apoplexy transsphenoidal decompression may even be indicated as an emergency procedure [78]. Nevertheless, in case of abundant suprasellar extension of macro- or giant-adenomas, the risk for leaving behind remnants is high. These residual masses may prolong symptoms and thereby reduce the possibility of the optic fibers to recover. Remnants may typically be hidden in descending folds of the sellar diaphragm and visualization by the microscope or the endoscope may be difficult [11]. Furthermore, possibly unnecessary manipulations of the diaphragm, which is often thinned due to the distension caused by the tumor, may lead to CSF leaks. Ultimately, blind probing into the suprasellar space may directly harm the optic nerves.

Through the use of iMRI these limitations in visualizing remnants which compress the optic nerves may be overcome. Generally, the suprasellar structures are more distinctively depicted, while primarily in low-field imaging intra- and parasellar remnants may be more difficult to detect. The specificity for low-field iMRI to detect remnants was reported to be about 90% and the sensitivity 100% [26, 27]. For high-field iMRI, a specificity and a sensitivity as high as 100% was reported [1]. In a study explicitly addressing the issue of early visual recovery after iMRI-controlled tumor resection in a low-field setting, 60% of the patients with residual tumors had persistent optic nerve compression on the first iMRI control scans [26]. An additional resection was possible in 56% of these patients. Ultimately the optic

apparatus was decompressed in 84% of the patients. The positive predictive values for VF and for VA recoveries if a decompressed optic chiasm was depicted by iMRI were both as high as 96%. For high-field settings, long-term data show improvement of VF and VA in up to 100% of the patients [1]. In iMRI-controlled reoperations VF and VA recovery were 86% and 74%, respectively [56]. One of the reasons for the lower rate in reoperated patients may be the longer duration of symptoms caused by persistent compression of the optic nerve structures; however, until now there is no controlled data supporting this thesis. Basically, a randomized trial may be able to compare the differences in the ophthalmological outcome caused by the use of iMR imaging; however, it may be questionable to which extent this could withhold the overt benefit of iMR imaging to these patients.

Deterioration of vision is one of the severe complications of transsphenoidal surgery. It was described by different authors, also after procedures guided by iMR imaging [30, 35, 48, 56]. Based on the reported rates in the studies summarized in Tables 1 and 2, the apparent incidence of postoperative decline of visual function may be below 1%; however, the comparison with study groups not using iMRI imaging remains difficult. It may be biased due to the different techniques applied and the variability of factors such as size, consistency and invasiveness of the tumors and duration of symptoms of the patients included. Nevertheless, while an incidence for ophthalmic function decline of 3% has been reported in a study using iMRI [79], the incidence in other studies without iMRI seems to be similar to those using iMRI [16, 20, 80-82].

3.3. Outcome of Hormonal Function

The dominant mechanisms of hypopituitarism are interruption of the hypophyseal portal vessels, compression of the pituitary stalk, and increased intrasellar pressure caused by tumor growth [83-87]. Therefore, surgical decompression of the pituitary gland and its stalk may lead to recovery of hypopituitarism. Predictive factors for better recovery rates include younger age, absence of arterial hypertension, lack of intraoperative CSF leak, pre-operative hyperprolactinemia and smaller tumor size [83, 88, 89]. The detection of gross total resection on postoperative imaging is a significant factor for postoperative hormonal recovery [90]. On the other hand, loss of pituitary function may be a complication of pituitary surgery. The rate of postoperative hypopituitarism in series on transsphenoidal tumor resections is commonly below 20% [63, 88, 89, 91-94]. Nevertheless, higher rates have been described [95-97]; especially in the case of larger or hormonally inactive tumors [88-90, 98] or pituitary apoplexy [99, 100].

Series of transsphenoidal surgery for pituitary adenomas with iMRI controls report an incidence of new hypopituitarism of 0-29% [27, 34, 36, 47, 48]. When comparing patients with NFA, who were operated in the iMRI to matched controls, the benefit in increasing GTR again becomes obvious. In a study focusing on endocrinological outcome, the first low-field iMRI scan showed GTR in 62% of the patients, which corresponds well to the results of postoperative MRI in the control group showing a GTR rate of 69% [27]. Additional tumor resection significantly increased the GTR rate in the iMRI-group to 85%. The question whether a possibly aggressive additional resection based on iMRI controls puts pituitary function at harm could be denied in this and in subsequent studies [1, 27, 56]. While the differences of new hormonal deficits (iMRI-group 29%, control group 45%), which was

generally high in this study, including mainly large and invasive NFA, did not reach statistical significance, there was however a tendency towards a smaller hormonal complication rate of iMRI-controlled surgery. Considering the recovery rates of tumor-induced hypopituitarism, a similar tendency towards a beneficial effect of iMRI was reported. As 59% of the patients in the iMRI-group showed some restoration of pituitary axis function, this was only detected in 45% of the controls. Predictive factors for a lower risk of pituitary function loss when the iMRI was used were age below 65 years, absence of cardiovascular risk factors (e.g., arterial hypertension and tobacco smoking) and pre-existing partial hypopituitarism [27]. Additionally, long-term data of patients operated in a high-field setting show quite dynamic results of the endocrinological outcome in those with NFA [1]. The development of hypopituitarism was detected in 11% of the patients 1 week after surgery; however, further loss was diagnosed in another 15% during a mean follow-up time of 5.6 ± 1.9 years. On the other hand, hormonal recovery was seen in 29% of the patients 1 week postoperatively and in another 48% of the patients at the end of follow-up. Radiotherapy-induced pituitary damage [101] may have influenced these results to some extent as 27% of the patients with late onset hypopituitarism were irradiated. This points out to the conclusion that repetitive testing of hormonal function is mandatory not only in iMRI-controlled, but in all NFA patients possibly suffering from hypopituitarism, as recovery or loss of function may happen not only in the initial but also in the later course after surgery [1, 102].

While reoperations may be a risk factor for loss of pituitary axes function, the reported rates for iMRI-controlled surgery do not exceed this range [56, 61]. In reoperated NFA with use of iMRI, endocrinological follow-up testing showed postoperative loss and recovery of hormonal axes in 12% and 15% of patients, respectively [56]. This recovery rate seems comparably low to series on primary surgeries; however, this may correlate with the lower GTR rate in reoperations as previously discussed [90].

In patients with intraoperative CSF leaks, craniopharyngiomas or Rathke's cleft cysts as well as transient or permanent diabetes insipidus may be detected more often [103]. The use of iMRI did not significantly influence the incidence of postoperative diabetes insipidus or syndrome of inadequate antidiuretic hormone secretion in a comparative cohort study including patients with NFA [27]. Nevertheless, the reported rates of diabetes insipidus (8%) and SIADH (5%) were comparably small when compared to the incidence in the general literature (18-30%) [62, 103-107].

3.4. Functioning Pituitary Adenoma

Acromegaly is caused by a growth hormone (GH)-producing pituitary adenoma. If excessive output of GH is not normalized, cardiovascular and metabolic disturbances as well as cosmetic and orthopedic deformities will result. Depending on the criteria for remission, transsphenoidal surgery in acromegaly leads to cure of the condition in 50-60% of the patients [41, 108-115]. Indeed, the size matters, as 75-95% of the patients with microadenomas, but only 40-70% of the patients with macroadenomas will show normalization of growth hormone excess. High preoperative growth hormone levels and invasive tumor growth configuration are two other significant predictors of an incomplete resection [108]. Persistent postoperative acromegaly may be accompanied by larger visible, either resectable or unresectable tumor remnants. Re-operations are reasonable only when tumor remnants that

seem to be resectable are detected. Nevertheless, due to postoperative changes in early MR-imaging, the sensitivity for detecting remnants is low during the first 3 months after surgery. While early imaging within 3 days postoperatively may still prove helpful [116], later images may become difficult to “read” due to scarring, fluid retention and changes of grafts applied for closure [117]. While growth hormone levels decrease rather rapidly within days, if surgery was successful, IGF-1 may decrease only after 1-2 weeks. That is why normally at the time when persisting acromegaly becomes probable, an immediate MRI to indicate an early reoperation before scarring takes place may not be helpful. Therefore, the results of iMRI scans, performed before the site is closed, may be valuable.

Intraoperative image quality is crucial for the evaluation of the intrasellar structures, and it was therefore postulated that the high-field setup would have definitive advantages over the low-field setups [47]. The only study, exclusively focusing on the outcome of growth hormone excess after transsphenoidal resection in a high-field setting, included 23 patients [47]. In 78% of the patients, complete tumor removal was intended; however, iMRI scans revealed tumor remnants in 44% of the operated cases, leading to an extended resection in 28% of them. This increased the rate of complete tumor removal and endocrine normalization from 33% to 44% using the consensus criteria [118], and improved endocrine outcome in another 17%. The comparability between postoperative MRI after three months and iMRI was excellent as none of the patients with remnants depicted on iMRI met the criteria for remission. In all cases with suspected cavernous sinus infiltration on iMRI, postoperative imaging after 3 months confirmed the parasellar remnants. If iMRI showed complete removal and no full endocrine remission was achieved, postoperative MRI after 3 months neither showed a remnant.

Surgery for GH-producing pituitary adenoma, applying an ultra-low-field iMR imaging modality, showed an overall remission rate of 67% [37]. In patients with primary surgery the remission rate was 74%; however, in previously operated patients the rate dropped to 20%. The remission rate was increased by 5% by additional resections based on iMRI scans. The patients’ characteristics of the already performed studies using high-field [47] or low-field iMRI [37] do not seem to be well comparable; thus, deductions which modality may be superior cannot be drawn from these results.

While there are studies including miscellaneous subtypes of functioning pituitary adenomas [41, 54], there is no study up to now reporting results on iMRI-controlled transsphenoidal surgery exclusively for Cushing’s disease or prolactinoma in a reasonable large patient group.

3.5. iMRI in Combination with Endoscopy

As stated above, visualization of the tumor and the related anatomy of the operating field is the key to successful transsphenoidal surgery. While the results of iMRI-controlled operations have been presented in this chapter, other techniques which may be used as a sole modality or in conjunction with iMRI have to be mentioned. As an additional tool for transsphenoidal surgery, the endoscope has been used more and more during the past decade. Numerous studies reported technical details, surgical results and its value in tumor visualization. In this context, several reports of endoscopically-assisted procedures, as an adjunct to low-field and to high-field iMRI-guidance for resection control, have been

published [1, 32, 38, 52, 56]. Considering tumor visualization, sensitivity and specificity for detection of remnants by high-field iMRI were reported to be 100% compared to postoperative MRI [1]. The endoscopic assessment of the resection rate before an iMRI-control scan was acquired in the same patients yielded a sensitivity of only 21% and a specificity of 78%. The remnants depicted by iMRI were found in the following localizations: lateral of the sella/cavernous sinus, 48%; suprasellar space, 28%; retrosellar space/clivus, 12%; in the sella, 12%. An additional resection based on the iMR images was made in 73% of these patients. Thereby the difference between the GTR rate (66%) on the postoperative MRI and the GTR rate (35%) detected by iMRI after endoscopically-assisted resection became very significant ($p < 0.0001$; OR 5.4, 95% CI 2.3-13.0).

In transsphenoidal reoperations the endoscopic assessment of GTR may even be more difficult, e.g., due to scarring and lack of anatomical landmarks. A study on transsphenoidal reoperations, which included a small subgroup of patients operated with endoscopic assistance used in a high-field iMRI-setting, reported that GTR was assumed in 40% of the patients based on the endoscopic assessment [56]. In another 40% of the patients partial resection was detected by the endoscope but further tumor removal did not seem possible. In the remaining 20% no definite statement about the extent of resection could be given. All of these patients showed tumor remnants on the subsequent iMRI control scans even those who were thought to be without remnants based on the endoscopic visualization. The localization of the remnants on the iMRI scans was as follows: lateral/in the cavernous sinus, 60%; suprasellar, 50%; intrasellar, 10%. Notably, an additional iMRI-guided resection was possible in 80% of these cases.

Previous studies raised similar points concerning false negative endoscopic findings, and uniformly reported an increase of GTR rates after further tumor visualization by iMRI [32, 38]. In contrast to the direct inspection by the endoscope, iMRI allows the evaluation of hidden structures which are not accessible by direct visualization (e.g., by being hidden in invaginations of the descending diaphragm or in the suprasellar space). The identification of tumor remnants may be even more facilitated by the possibility of comparing pre- and intraoperative images that are acquired in the same position of the device. Compared to the iMRI, the endoscope may be less cost intensive. Nevertheless, the benefit of a complete resection in these mostly benign tumors weakens arguments about costs. While most studies on iMRI were not weighed towards the analysis of cost efficiency, the significantly higher GTR rate made possible by iMRI controlled surgery resulting in a lower rate of reoperations or additional therapies (e.g., radiotherapy) is indeed noteworthy.

4. PROS AND CONS

4.1. Specificity and Sensitivity of Tumor Detection

Visualization is the key; however, the surgeon has to remind himself that not everything that he detects with whatever tool used to visualize tumor remnants is really what it seems to be. False-positive iMRI findings may provoke unnecessary probing for remnants and increase the risk of hypopituitarism and CSF leakage. Both the specificity and sensitivity of iMRI for

detection of residual sellar lesions were subject of debate in several studies [1, 26, 27, 30, 31, 35, 56, 119]. The following reasons for misinterpretations have been reported:

1. The iMRI fails to give sufficient imaging results due to “noise”
2. Gadolinium enhancement is poor
3. Image layering misses the tumor
4. Poor resolution due to low field strength
5. There is difficulty in differentiating remnants of sellar tumor from intrasellar blood products and blood within the venous sinus. Specificity and sensitivity reported for both low- and high-field iMRI are commonly in the range of 90-100% and 75-100%, respectively.

It seems that most often coagula may be misinterpreted as residual tumor. In low-field settings pituitary adenoma and blood products often have an isointense aspect in non-enhanced T1- and T2-weighted images. If gadolinium is administered a difference may be observed during the first control scan. Nevertheless, in the case of repeat imaging the accumulated blood may be mixed with contrast agent and reliable differentiation may not be possible anymore. There are several technical tricks to facilitate image interpretation. Pooling of blood may be prevented by applying bone wax as a temporary reconstruction of the sellar floor [31]. In small adenomas the resection cavity may be filled with a small wax ball and the localization and extent of the ball may be compared to the tumor localization on the scans acquired before resection. Another technique to enhance the contrast is packing of the tumor resection cavity with contrast-soaked cotton pledgets and filling the remainder of the space with gauze [45].

4.2. Time and Cost Efficiency

One of the common arguments used by sceptics against iMRI-controls in transsphenoidal surgery is the additional time needed for the scans. Nevertheless, the duration of the control scans is often overestimated. Most devices provide short scanning sequences to verify the scanner’s correct position before a longer sequence is started. For the Medtronic PoleStar™-unit there is e.g., the eSteady sequence, which is acquired in 24 seconds. The Siemens Magnetom Sonata™ provides a shortcut via the HASTE sequence, which takes 20 seconds. In case of a remnant already depicted by these sequences, surgery may be continued without further detailed time-consuming imaging. More detailed scan sequences (e.g., the T1-weighted contrast enhanced 3mm scan of the Medtronic PoleStar™-unit or the T2-scan of the Siemens Magnetom Sonata™) will take about 10 minutes and may be immediately transferred to the neuronavigation sequences without further referencing. Thus, the mean duration for draping, scanning and return to the surgical field is about 15 minutes. Depending on the number of intraoperative scans needed, the use of an iMRI will prolong the procedure by 15-30 minutes in most cases [36, 56]. Nevertheless, the operating time will also be prolonged by the consecutive additional resections, which obviously would not have been made without the use of iMRI. Thus, the operating times of procedures with and without iMRI may not be well comparable. Until now, no tendency of an increased complication rate caused by the prolonged operation time was detected [12]. Ultimately the surgeon has to ask the question

whether the goal is to increase the chances for a GTR during the first procedure which will take some extra time or whether the operating time is better used for the reoperation if a resectable remnant keeps on growing.

Due to the additional time needed, in case this technology is used, it may be reasonable to use selection criteria for indicating the use of iMRI in transsphenoidal pituitary surgery. This may even be mandatory in high-impact centers, as operative capacity in the iMRI may be lower than the number of patients asking for treatment. A proposal which patients benefit from iMRI-controlled procedures has been made and includes the following points [1]:

1. History of previous transsphenoidal surgery (e.g., with presence of massive scarring and loss of anatomical landmarks)
2. Invasive tumor growth pattern (e.g., into the clivus or the cavernous sinus, Knosp grades 3 or 4)
3. Abundant suprasellar or retrosellar tumor growth (modified Hardy's grades 3 or 4) [6, 120] with consecutive high probability of incomplete resection and/or persisting symptomatic remnants (e.g., dumbbell-shaped tumors)
4. Tumors that need extended transsphenoidal approaches (e.g., subfrontal, transclival).

An additional drawback for the use of iMRI is the considerable equipment cost. This may be an issue more dominated by medico-economic arguments, than influenced by the results of the individual operative procedures which, as has been shown in the previous pages, are significantly enhanced by the use of iMRI. Of course the iMRI suites are not exclusively used for transsphenoidal surgery. Concurrent with the quoted results of its use for pituitary tumors, numerous studies have reported the benefit in several other cranial procedures. Promising results have e.g., been reported for iMRI-controlled resection of low and high grade glioma [121-123] and in epilepsy surgery [124, 125]. Depending on the case load and case mix of a department, the concept of an iMRI may be very reasonable. Given by the fact that informed patients often seek treatment in specialized departments with availability of intraoperative imaging techniques, the thereby provoked increase in cases may once more improve the affordability of such a device.

The true value of iMRI in transsphenoidal pituitary surgery may ultimately only be determined by randomized studies. Ironically, due to the excellent results provided by the studies presented above, this will be difficult to accomplish. Surgeons as well as patients with tumors suitable for iMRI-controlled procedures will want to use this technology and artificially withholding an obvious benefit is simply not justifiable.

ABSTRACT

The optimal management of inguinal hernia (IH) in patients with liver cirrhosis (LC) with or without ascites remains a matter of debate. There are very few references to the incidence and natural history of IH in patients in this setting. In this chapter, we present a review of the current literature.

In the seven reports of the repair of IH in patients with LC published to date, the best level of evidence observed is IIb. In the light of the results we stress the importance of preoperative optimization, including management of ascites, hemostatic disorders and infections. If possible, procedures should be performed under local anesthesia. Herniorraphy and hernioplasty obtain good results. It is important not to open the hernia sac; if it is necessary to do so, suturing is essential.

Morbidity and mortality rates after IH repair are worse in cirrhotic than in non-cirrhotic patients. Mortality ranges from 0 to 2.7%, and occurs mainly in emergency procedures, while morbidity ranges from 6.2 to 36.4%. Several authors have postulated that morbidity is not related to the Child-Turcotte-Pugh (CTP) score or to the presence of ascites. The recurrence rate described is between 0 and 11%. The repair of symptomatic IH in patients with LC improves their quality of life, especially in the case of CTP class C patients and in patients with refractory ascites who often present severe symptoms

associated with their IH. Elective repair of IH in patients with LC requires careful surgical technique and perioperative care.

1. INTRODUCTION

The prevalence of chronic liver disease and liver cirrhosis (LC) has risen in recent years, due to the global obesity epidemic, alcohol abuse, and viral hepatitis [1]. Regarding hernias of the abdominal wall, the most common types in cirrhotic patients are umbilical and incisional, followed by inguinal [2]. The main problems facing surgeons in these patients are coagulation, infection and delayed wound healing [2]. As a result, cirrhotic patients present a higher surgical risk and surgeons are often reluctant to operate.

The optimal management of LC patients with IH with or without ascites remains a matter of debate. The incidence and the natural history of IH in patients with LC have not been clearly documented [3], and in fact there are very few references to this problem in the literature.

2. METHODS

We performed a search of articles published in PubMed until December 1, 2014 in all languages, with keywords (MeSH): hernia, inguinal and liver cirrhosis. All types of study were included. The search details were: ("hernia, inguinal" [MeSH Terms] OR ("hernia" [All Fields] AND "inguinal" [All Fields]) OR "inguinal hernia" [All Fields] OR ("hernia" [All Fields] AND "inguinal" [All Fields]) OR "hernia, inguinal" [All Fields]) AND ("liver cirrhosis" [MeSH Terms] OR ("liver" [All Fields] AND "cirrhosis" [All Fields]) OR "liver cirrhosis" [All Fields]). Our first search identified 31 papers. References of these 31 papers were also investigated. All the papers related to the topic of this chapter were used. Finally, only 30 papers were included in the study.

3. INGUINAL HERNIA INCIDENCE IN PATIENTS WITH LIVER CIRRHOSIS

The incidence of IH in patients with LC has not been established, but it appears to be higher than in the general population, especially in patients who also present severe ascites [3,4]. It has been postulated that the increased intra-abdominal pressure due to ascites distends the peritoneum in sites that support the abdominal wall, thus producing hernia [5].

In Denmark (a country with a population of 5.2 million) Hansen et al carried out a follow-up study of patients treated from 1993 to 1997 identified from the Danish National Hospital Register, which contains information on all hospital admissions since 1977. These authors recorded 22,840 patients with a diagnosis of LC, of whom 741 (3.24%) had an IH [6].

4. PATHOGENESIS AND EVOLUTION

The formation of abdominal hernias in patients with LC is linked to an increase in intra-abdominal pressure due to several factors: ascites [7,8], the weakness of the abdominal wall due to changes in protein metabolism, and vascular changes associated with decompensated portal hypertension [8]. However, some authors claim that, with the exception of umbilical hernias, IH are not markedly influenced by the presence of ascites [2,9,10]. Furthermore, it appears that ascites may prevent strangulation, which may occur when large volumes of ascites fluid are extracted quickly. An incarcerated IH is rare in patients with ascites [9,10].

This opinion, presented in Hurst et al's paper [11], has received support from other authors [5,9]. In Hurst et al's study, three of the 11 patients were operated on urgently. Two of the three incarcerated hernias were diagnosed in patients with well-controlled ascites; the third patient suffered a femoral hernia, and so no relationship between ascites and complications was seen [11]. In the series of Gillet et al (26 patients with LC and IH) incarceration occurred in three [12]. None of these patients required intestinal resection, and none of the patients with LC and IH had uncontrolled ascites [9].

If left untreated, defects of the abdominal wall in LC patients can grow to an immense size and may be associated with necrosis of the overlying skin due to pressure, skin rupture, leakage of ascites, and bacterial peritonitis [7].

The IH may lead to a clear deterioration in the quality of life of patients with LC, but repair improves it markedly [13,14]. Patients with decompensated cirrhosis often have severe symptoms, because ascites enters the hernia sac, and the hernia enlarges progressively, often becoming painful. It may hinder deambulation and often forces the patient to stay in bed [14].

5. PREOPERATIVE MANAGEMENT

Several preoperative measures have been recommended in these patients.

1. Doppler Ultrasound: In the preoperative study Doppler ultrasound has been recommended to avoid the possibility of a mistaken diagnosis. Sometimes, massive venous dilations entering the spermatic cord at the internal inguinal ring can simulate a hernia. Doppler ultrasound is mandatory when diagnosis is doubtful, in order to avoid an unnecessary surgical intervention [15].
2. Medical history: Extensive preoperative evaluation is essential to improve management of ascites, coagulopathy and platelets.
3. Ascites: Many authors have stressed the need to provide intensive treatment for ascites before IH surgery, especially in cases of refractory ascites [3,9,11,14]. Refractory ascites is defined as lack of body weight response (loss of body weight less than 200 g/day after 4 days) to sodium restriction (50 mEq/day) and high doses of diuretics (400 mg spironolactone per day plus 160 mg furosemide per day) or the development of diuretic-induced complications that preclude the use of effective diuretic dosage [16].

Belghiti et al. initiated medical treatment including a low-sodium diet and diuretics. When this is effective, surgical herniorrhaphy can be performed electively after ascites has been controlled; the procedure is associated with low mortality and morbidity. These authors also stressed that abdominal ultrasound examination should always be performed in order to confirm the elimination of ascites [9]. In Hurst et al.'s series of 18 patients, the treatment of ascites included fluid restriction (n=16 patients), diuretics (n=16), large-volume paracentesis (n=5), and peritoneovenous shunt (n=2). Only one of the patients requiring large-volume paracentesis and none of those that underwent peritoneovenous shunting required surgery [11]. Patti et al. all treated all patients with ascites with higher doses of diuretics, (spironolactone 400 mg per day and, 160 mg per day of furosemide), and sodium restriction (50 mEq/d). This medical management was continued until the disappearance of ascites, and then patients were operated [14]. Oh et al. controlled ascites with diuretics or intermittent tapping [3].

4. Hemostasia: Abnormalities of hemostasis in the LC are complex and multifactorial and may predispose to prolonged bleeding after invasive procedures. Therefore, LC patients should undergo elective surgery after completing medical optimization, and rapid evaluation and correction of hemostatic abnormalities are recommended [7]. However the correction of the platelet count and INR before surgery is controversial; there are no specific guidelines regarding surgical procedures such as inguinal hernia repair. Furthermore, at many centers that perform liver transplantation, it is standard practice not to administer blood products before or during the procedure except in the case of active bleeding [17]. The American Association for the Study of Liver Diseases (AASLD) guidelines for liver biopsy (transcutaneous or transvenous) state that platelet transfusion should be considered when levels are less than 50,000-60,000/ μ L. The use of prophylactic measures or rescue strategy such as plasma, fibrinolysis inhibitors, or recombinant factors should be considered only in specific situations, and in fact their effectiveness remains to be established [18]. The Society of Interventional Radiology guidelines recommend correcting an INR greater than 1.5 and a platelet count less than 50,000/ μ L [19]. Weeder et al proposed abandoning the old practice of prothrombin time and platelet count-guided prophylactic transfusion and to adopt the following guidelines, which are now increasingly accepted in liver transplantation care [17]:

- Pre-procedural phase: no prophylactic correction of hemostasis; treat existing infections and optimize renal status.
- Intra-procedural phase: treat only active hemostatic bleeding with transfusion or antifibrinolytics; maintain low central venous pressure and normothermia, calcium and pH.
- Post-procedural phase: restore central venous pressure to normal values, detect and treat thrombotic or bleeding complications.
- Apply thrombosis prophylaxis during these three phases.

Desmopressin (vasopressin 1-desamino-8-D-arginine (DDAVP)), has been shown to be safe and effective for the prevention and treatment of bleeding in cirrhotic patients [20]. In a prospective study by Koscielny et al. of 13 patients with LC, platelet dysfunction was

corrected in 11 cases (84.6%). Bleeding time after DDAVP administration was corrected in nine [21]. Prophylactic treatment with DDAVP should be administered approximately one hour before the scheduled surgery. Postoperative treatment with repeated doses of 12-24 hours after the procedure should be considered until wound healing [22].

5. Antibiotics: Few authors report the use of prophylactic antibiotics one hour before the operation. Several antibiotics have been used: ceftazidime 2 g intravenously [14] or cefazolin 1 g intravenously [3,13]. Gubitosi et al. used ceftriaxone in 39 patients and amoxicillin/clavulanic in 13 others just before surgery [2]. The prophylactic administration of antibiotics to patients with LC is known to reduce mortality and increase hemostatic function, but the exact mechanism is unknown. The adequate surveillance for and treatment of infections before invasive procedures is therefore recommended [17].

6. ANESTHETIC AND SURGICAL TECHNIQUES

Local anesthesia has been widely advocated and used in the surgical repair of IH in patients with LC [2,13,14,23,24]. Pere et al. noted the risks of spinal and epidural anesthesia: 1) spinal or epidural anesthetics should not be given to patients with severe coagulation disorders, because of the risk of epidural hemorrhage. 2) Vasodilation and relative hypovolemia, typically found in LC patients, worsen with spinal or epidural anesthesia. Pere et al. reported two cases of LC with controlled ascites whose condition deteriorated severely after elective inguinal herniorrhaphy in which spinal anesthesia was performed, and one exitus in whom epidural anesthesia was used [5]. If a central block is chosen, adequate monitoring, volume loading, and inotropic support are essential to maintain adequate blood pressure and visceral perfusion [5].

Few authors have included hernia repair technical details in their papers. Here we summarize the most relevant tips and tricks:

Gubitosi et al. [2]: a series of 52 LC patients with IH. Minor complications occurred in five patients. They used the following technical measures:

- Cross-matched platelet transfusions were given to 19 patients (36.53%) preoperatively (except in one case), and intra- and postoperatively.
- The hernia sac was not opened.
- Surgical Technique: Prolene Hernia System (PHS) Gilbert (6 cases), Trabucco (37), and Lichtenstein (9).
- After inserting the mesh and performing adequate hemostasis, 2-5 ml of human fibrin glue (Tissucol®) was applied in 42 patients. The application of fibrin-glue significantly reduced the rate of complications.
- The aponeurosis of the external oblique muscle under the funicular structures was closed when repair is finished.
- Elastic adhesive bandages from the pubis across to the anterior superior iliac spine were applied at the end of the operation (Thensoplast®).

Patti et al. [14]: 32 LC patients undergoing IH repair. During the in-hospital postoperative time, two inguinoscrotal hematomas were diagnosed (6.25%). The technical details were:

- The hernia sac was carefully isolated from the related structures in order to avoid perforation and, subsequently, it was invaginated without opening the abdominal cavity. Large hernia sacs were cut, sutured and invaginated at the internal inguinal ring to avoid the risk of ascitic leak.
- All patients were operated with a Lichtenstein hernioplasty using a polypropylene mesh.
- The fascia was closed with a running suture using a nonabsorbable monofilament.
- A suction drainage was inserted if the dead space was large and if refractory ascites was present. No ascites leakage from the surgical wound or wound infection was observed in postoperative period.

7. MORBIDITY AND MORTALITY

Surgery in patients with LC is classically associated with increased mortality and morbidity. A large study in the United States (1999-2004) assessed the results of repair of abdominal wall hernias (excluding IH) in cirrhotic versus non-cirrhotic patients. Data from 30,836 cirrhotic patients were included and compared to 1,197 non-cirrhotic patients [7]. LC patients had significantly longer hospital stay, and higher morbidity (16.5% vs. 13.8%) and mortality (2.5% vs 0.2%) than non-cirrhotic patients. Moreover, patients with LC underwent emergency surgery more often (58.9% vs. 29.5%) and associated morbidity rates were also higher (17.3% vs. 14.5%). Differences in elective surgical mortality in patients with cirrhosis approached statistical significance (0.6% vs 0.1%), and mortality was seven times higher in emergency procedures (3.8% vs. 0.5%). Several associated comorbidities increased mortality in patients with LC: functional impairment, congestive heart failure, renal failure, nutritional deficiencies, and peripheral vascular disease. The study concluded that, ideally, patients with cirrhosis should undergo elective hernia repair after medical optimization.

In a systematic review of morbidity and mortality after non-hepatic surgery in patients with and without LC, de Goede et al. found a higher postoperative morbidity and mortality in cirrhotic patients. Cholecystectomy and umbilical and inguinal hernia correction were associated with the lowest increases in morbidity and mortality, while pancreatic surgery, cardiovascular and trauma surgery presented the highest differences between groups. The preoperative model for end stage liver disease (MELD) and CTP scores appeared to be predictive of postoperative risks. Portal hypertension and emergency surgery were associated with increased mortality and morbidity rates [25].

There is no consensus regarding morbidity and mortality rates in patients with IH and LC. Classically, it was believed that hernia repair in this population is plagued with wound complications such as persistent ascitic fluid leakage through the incision and the wound infection and mesh, and recurrence of the hernia [6,9, 10,11].

Belghiti et al. stated that patients with IH and LC without ascites or with moderate ascites were candidates for elective surgical repair and that mortality and morbidity rates were low.

Moreover, in patients with refractory ascites, surgical repair is associated with high mortality and morbidity. Ascites may cause postoperative infection, thus delaying healing. Besides, severe complications such as strangulation are uncommon in patients with IH and LC; therefore, these authors did not recommend surgical repair in patients with refractory ascites and without hernia symptoms [9].

In the study by Hansen et al. [6], 256 patients with IH and LC underwent surgery. The control group consisted of a sample of 741 Danish patients over 20 years of age who underwent the same operative procedure as the IH/LC patients on the same day. Seven patients (2.7%) died within 30 days, compared with five (0.7%) in the control group. The adjusted odds ratio for 30-day mortality was 4.4. However, very few clinical data (reason for surgical indications, details about the operation, anesthetic procedures, stage of LC, ascites, smoking habits, alcohol consumption or cause of death) were reported and so no firm conclusions can be drawn from the results.

Morbidity and Mortality, and Results of published series:

The literature search revealed seven series of IH repair in patients with LC (Table 1).

Hurst et al.: Hurst et al retrospectively reviewed the records of 18 cirrhotic patients with ascites and groin hernias (20 inguinal and one femoral). Eleven patients underwent repair of their groin hernias (13 repairs). Ten herniorrhaphies were performed electively; two were performed urgently for recent difficult reduction, and one was performed urgently for incarceration without strangulation. There were four minor postoperative complications: two minor wound complications, one episode of readily correctable prerenal azotemia, and one case of mild and reversible postoperative hepatic encephalopathy. There were no ascites leaks, and no perioperative mortality. Twelve groin hernia repairs were followed for 25 months (mean). One recurrence (8%) occurred 11 months after surgical repair. In eight patients, herniorrhaphy was performed when ascites was well controlled. Although five hernias were repaired in the presence of clinically significant ascites, the ascites either persisted or recurred at some time in the postoperative course in all but two cases. The results of this retrospective study suggest that serious complications from groin hernias in LC are uncommon, and that elective repair can usually await control of ascites. Additionally, for selected patients with ascites, elective inguinal hernia repair can be performed safely with an acceptable rate of recurrence [11].

Park et al: In Park et al.'s series, 53 patients underwent surgery for abdominal wall hernias (42 IH, seven umbilical hernias and two incisional hernias). Seventeen patients were Child–Turcotte–Pugh (CTP) A, 27 patients CTP B, and nine CTP C. The median follow-up was 24 months. There was only one 30-day postoperative death in a CTP C patient, and no CTP deterioration after 30 days of operation. There was no mortality or recurrence in 17 patients with medically refractory ascites. The difference in 30-day mortality according to CTP class and the presence of refractory ascites was not statistically significant [13]. The authors concluded that IH operation was safe in CTP A and B, with low rate of recurrences, and that there was no clear increase in the operative risk in class C. In addition, refractory ascites did not increase the operative risk or the recurrence rate. Therefore, surgical repair may be recommended even in patients with refractory ascites and poor hepatic function in order to prevent life-threatening complications or severe pain. However, others have reported high mortality and morbidity with surgical repair of inguinal hernia in patients with refractory ascites this procedure [9,11].

Table 1. Reported series of inguinal hernia repair in patients with liver cirrhosis

RA: refractory ascites; OA: ascites at the moment of operation; CTP: Child-Turcotte-Pugh scores; SA: spinal anesthesia; GA: general anesthesia; LA: local anesthesia.

Patti et al: Thirty-two cirrhotic patients undergoing inguinal hernioplasty were evaluated. The same surgeon performed all hernioplasties. In eight patients, hernioplasty was performed under local anesthesia and the remaining 24 were treated under general anesthesia. All patients received a tension-free Lichtenstein hernioplasty. During the postoperative in-hospital course, two inguinoscrotal hematomas appeared, both in a CTP B patient without ascites [14].

Lawson et al.: Lawson et al. conducted a retrospective review comparing patients with LC who underwent groin herniorrhaphy and patients who underwent inguinal herniorrhaphy after liver transplantation. They reported 43 inguinal herniorrhaphy procedures, 18 in 18 documented LC and 25 in 24 patients after liver transplantation. The mean follow up was 33 months. Two IH recurred in the LC group, at 15 months and at 7 years after repair (relapse: 11%), and none after liver transplantation. Both patients had undergone repair without a mesh. There were no deaths, major complications, reoperations, ascitic leaks, or infections in either group. Minor complications in the LC group included hematomas in two patients and seroma in one (17%); one hematoma was the only complication in the liver transplantation group (4%). The authors concluded that groin herniorrhaphy with or without a mesh is a safe and durable procedure in patients with LC and after liver transplantation [23].

Oh et al: The retrospective study performed by Oh et al. [3] compared 129 symptomatic patients with IH and LC who underwent surgical IH repair (McVay) performed by the same surgeon with 760 non-LC patients. Complications occurred in 14/129 (10.9%) patients with LC, but all these complications were resolved conservatively. Complications also developed in 44 (6.8%) of the non-LC controls. The complication rate for patients with LC was not significantly higher than for non-LC controls ($P = 0.11$). In the LC group, complication rates were not related to CTP class. LC patients with ascites at the time of the operation developed more postoperative complications than those without ascites, but the difference was not significant (LC-ascites: 10/81, 12.3% vs. LC-non-ascites: 4/48, 8.3%; $P = 0.57$). There was no leakage of ascites. Two CTP class C patients (1.55%) died in the postoperative period due to liver failure. For patients with LC, the median follow-up was 22.9 months (mean: 38.1 months; range 0.6 to 129.5 months) and recurrence occurred in three patients (2.3%) (two CTP B and one CTP C). Although all recurrent hernias developed in patients who had ascites at the time of the initial operation, no significant differences in recurrence rates were found between patients with and without ascites (3.7% vs. 0%; $P = 0.29$). The median time to recurrence was 30.9 months (range, 26.7 to 37.2 months), and all recurrent hernias were repaired successfully. For non-LC controls, the median follow-up was 30.1 months (mean: 39.4; range: 0.5 to 134.6 months), and there were no significant differences in the duration of follow-up with regard to the LC group ($P = 0.68$).

The recurrence rate was 2.3% ($n = 15$), and cumulative recurrence rates did not differ significantly between LC patients and controls (0 vs. 1.2% at 1 year, 3.6 versus 2, 2% at 3 years, and 5.7 vs. 3.6% at 5 years; $P = 0.87$). This study shows that IH repair carries a higher risk of postoperative complications and recurrence in cirrhotic than in non-cirrhotic patients. In addition, complications and recurrence rates were independent of CTP class. The authors suggested that patients with symptomatic IH LC should be considered for elective surgical repair.

Gubitosi et al: Gubitosi et al. [2] studied 52 LC patients undergoing IH repair between January 2007 and January 2009. Repair was performed by the same surgeon: the main end-point was to assess the effectiveness and safety of surgical treatment with certain

perioperative measures. Day-surgery was performed in 25 patients. Average hospital stay was 3.1 days (2-7). There was no mortality, no intraoperative complications and no surgical infection. The postoperative complication rate was 9.6%: seromas/serohematomas, serohematic congestion spermatic cord, and postoperative neuralgia (one patient).

There were no statistically significant associations with ascites, the number of hernias, or the type of defect; only hernia size was associated with complications. Patients with CTP C had a higher rate of complications, but as in other series [7,14,26] the difference was not statistically significant. The application of fibrin-glue significantly reduced the rate of complications and need for platelet transfusion. The type of admission (regular inpatient or day surgery) had no significant effect on the complication rate [2].

Hur et al. These authors retrospectively reviewed the medical records of 22 patients with LC and ascites (no cases of refractory ascites) who underwent IH repair with mesh plug performed by the same surgeon under local anesthesia. Minor complications occurred in only three patients (13.6%): two hematomas, and one case of swelling of the scrotum. These complications resolved spontaneously without blood transfusion or reoperation [24].

8. QUALITY OF LIFE

IH and LC impair quality of life (QOL). QOL is reduced by the presence of IH in patients without LC [27] and improves after repair [28,29]. LC also reduces QOL [30], and surgical repair of IH in patients with LC improves it [13,14].

The study by Patti et al. [14], of 32 LC patients undergoing inguinal hernioplasty showed that the scores on all eight domains of SF-36 and two comprehensive indexes of SF-36 – Physical Component Summary (PCS) and Mental Component Summary (MCS) – improved notably after hernioplasty, especially in CTP class C patients and/or with refractory ascites. This improvement was most evident for bodily pain, physical role, social functioning, and overall health. The improvement in the PCS was more notable in patients with refractory ascites compared to those with the treatable form (40.2% versus 17.7%). The results for the MCS were even more striking (61.1% vs 6.8%) in all Child's classes, and CTP C patients presented a particularly high increase of 61.3% between preoperative and postoperative score.

In Park et al's series, in the follow-up interview all 53 patients (100%) reported that hernia operation increased their QOL [13].

CONCLUSION

The ideal management of IH in patients with LC is not clearly established. After this review of seven published series we draw the following conclusions:

- Optimal preoperative management of ascites, hemostasis disorders and infections is required.
- Use of local anesthesia is recommended.
- Free-tension techniques should be performed.

- In principle, the hernia sac should not be opened; if it has to be opened, or if it is opened accidentally, it must be repaired.
- Morbidity and mortality of IH repair are higher in patients with LC:
 - Morbidity: 6.2 to 36.4%. Several authors affirm that morbidity is independent of CTP [3,6,14] and is unaffected by the presence of ascites [7,9].
 - Mortality: 0 to 2.7%. One study reported an overall mortality of 2.7% after inguinal hernia repair compared to 0.7% for non-cirrhotic patients (OR 4.4) [6]. Mortality occurs mainly in emergency procedures.
- Recurrence is between 0 to 11%.
- Repair of symptomatic IH in patients with LC improves their quality of life [13,14] particularly in patients with CTP C and in patients with refractory ascites [14]. In patients with high MELD scores and awaiting liver transplantation, hernia repair should be delayed until after transplantation, or during this procedure in some selected cases [23].

Elective repair of IH in patients with LC requires careful technique and intensive perioperative care.

Chapter 377

ERECTILE FUNCTION AFTER FEMALE-TO-MALE TRANSSEXUAL SURGERY

Borko Stojanovic, Marta R. Bizic and Miroslav L. Djordjevic*

School of Medicine, University of Belgrade, Serbia

ABSTRACT

Neophalloplasty is one of the most difficult surgical procedures in genital reconstructive surgery. Many different tissues have been applied such as local vascularized flaps or microvascular free transfer grafts. The main goal of the neophalloplasty is to construct the functional and cosmetically acceptable penis. Although voiding while standing is a priority for most female-to-male transgenders, most patients want to use the neophallus for sexual experience. Erectile function in male transgenders is based on erogenous sensitivity and possibility to achieve erection. In transgenders who underwent metoidioplasty, erogenous sensation is fully preserved while the erectile size of the reconstructed clitoris is not enough for penetration. In patients with total phalloplasty, erectile dysfunction is occurred due to the lack of erectile tissue and penile prosthesis implantation presents a suitable option. Two types of penile prostheses, semi-rigid and inflatable, are usually used after total phalloplasty. Different techniques have been described to enable insertion of both types of prosthesis, but they often resulted in complications and failure. The main limiting factor is presented by the fact that there is no adequate substitute for the penile erectile tissue after phalloplasty. In contrary to serious complications reported in the past, new techniques and modifications for penile prosthesis implantation into the neophallus seem to be safe in experienced hands.

Keywords: neophalloplasty, radial forearm free flap, musculocutaneous latissimus dorsi flap, erectile function, penile prosthesis, complications

INTRODUCTION

The term transsexual came into professional and public usage in the 1950's as defining a person who aspired to or actually lived in the anatomically contrary gender role, whether or not hormones had been administered or surgery had been performed. In recent years, there has been an increase in the awareness and acceptance of the transsexuals. In the International Classification of Diseases (ICD-10) '*transsexualism*' is described as a desire to live and be accepted as a member of the opposite sex, usually accompanied by a sense of discomfort with, or inappropriateness of, one's anatomic sex, and a wish to have surgery and hormonal treatment to make one's body as congruent as possible with one's preferred sex. Therefore, genital sexual reassignment requires the combined team efforts of a psychiatrist, an endocrinologist, a plastic surgeon, a gynecologist and an urologist. Sex reassignment surgery (SRS), either male to female or female to male, is the last step in an individual's transition and includes surgical procedures that will reshape the individual's body into a body with the appearance of the desired gender [1, 2].

Prior to SRS, all patients need to have complete psychiatrist evaluation for the further hormonal and surgical treatment and documents called Standards of Care for Gender Identity Disorders (SOC). The most widespread SOC in this field is published by the World Professional Association for Transgender Health (WPATH) [3]. All patients have to have undergone medically supervised hormonal treatments before commencing the surgical procedures. Female to male transsexuals need to start with testosterone use to enlarge the clitoris, deepen the voice and produce facial and body hair. In female to male transsexuals definitive sex reassignment surgery involves chest reconstruction, removal of female reproductive organs and creation of a neophallus.

Bilateral mastectomy is very often the first, and in many cases the only surgical procedure that female to male transsexual patients undergo. Breasts are one of the mostly visible symbols of the female body, and therefore represent the main psychological problem of these patients. Removal of female reproductive organs (hysterectomy and bilateral salpingoophorectomy) can be performed either before or at the same time with phalloplasty. It can be performed using either abdominal, transvaginal or laparoscopically assisted approach. Removal of the vagina is presented by destruction of mucosal and submucosal part of the vagina so called colpocleisis and followed with reconstruction of the perineum to be as in males [4, 5].

Reconstruction of the neophallus is one of the most difficult elements in surgical treatment of female transsexuals. While there are a variety of available surgical techniques, their results are not equally acceptable to all patients. The preference for a specific surgical technique mostly depends on the patient's desires and expectations [6]. Nevertheless, it is the surgeon's duty to fully inform the patient about all advantages and disadvantages, as well as all complications that might occur after surgical procedure and their potential severity and even to talk them out of a desired surgical technique if there are contraindications. Although voiding while standing is a priority for most female-to-male transgenders, most patients want to use the neophallus for sexual experience. The main limiting factor is presented by the fact that there is no adequate substitute for the penile erectile tissue after phalloplasty. Different techniques have been described to enable neophallic rigidity, but they often resulted in complications and failure [7].

TECHNIQUES OF PHALLOPLASTY

Metoidioplasty

This is a technically demanding and challenging surgical procedure used in female to male transsexuals who want a gender reassignment surgery without undergoing a complex, multi-staged surgical creation of an adult size phallus. It represents a technique for creating a neophallus from a hormonally hypertrophied clitoris in female to male transsexuals who do not wish to have sexual intercourse (Figure 1) [8]. The clitoris and penis are homologues, like the labia majora and the scrotum, even though sited in a different position. Durfee and Rowland were the first to report surgical penile substitution using the clitoris in female transsexuals [9]. The techniques have been refined since then, and Laub et al. defined this surgical transformation as metoidioplasty derived from the Greek words 'meta', 'toward' and 'oidion', 'male genitalia' [10]. Selecting metoidioplasty as a surgical procedure will limit scarring to the external genital region. Hage reported that even though metoidioplasty represents an essentially one-stage procedure, even with this technique, phalloplasty for female to male transsexuals can hardly be completed in one step. Therefore, metoidioplasty is a method of choice in all cases where the clitoris is large enough to provide a neophallus with all functions of a penis [11]. We have published the results of metoidioplasty in 22 patients, with a mean follow-up of 3.9 years, during which 3 urethral fistulas and two strictures were encountered [12]. Therefore, a continual challenge in the search for new and better solutions resulted in many modifications of our original technique with the aim of changing the feminine appearance of the external genitalia to a more masculine morphology and of allowing voiding while standing.

Figure 1. Appearance of genitalia in female to male transgender. Clitoris is hormonally enlarged.

Advancement of the clitoris begins with circular incision beneath the clitoral glans, at the border between the inner and outer layer of the clitoral prepuce and continues around the urethral plate and native urethral orifice. After total degloving, fundiform and suspensory clitoral ligaments were detached from the pubic bone to advance the clitoris, so it would become mobile to enable the new fixation at the base of the neophallus. Urethral

reconstruction begins with the reconstruction of the bulbar part of the urethra. Remaining part of the anterior vaginal wall is anastomosed with the remaining urethral plate, forming the bulbar part of the urethra. Further urethral reconstruction includes using of all available genital tissue, both labia minora, and hairless clitoral skin. The inner surface of both labia minora is dissected to create a flap with appropriate dimensions without detachment from the outer labial surface. This way, excellent vascularization of the flap is enabled. Flaps are joined to create a tube and to lengthen urethra from its bulbar part. More length of the urethra is achieved using available clitoral skin. Both varieties of flaps, clitoral and labial, have fine supportive tissue that prevents fistula formation and give satisfactory aesthetical results. Finally, new urethral meatus is placed at the base of the neophallus. At the end, vaginal space is closed and perineum is created to be as in males. Both labia maiora are joined in the midline over the neourethra creating the one-sac scrotum. Silicone testicle prostheses are inserted in both labia maiora completing scrotoplasty (Figures 2-4).

Figure 2. Appearance of genitalia after metoidioplasty.

Figure 3. Good relationship between neophallus and scrotum with implants is visible.

Figure 4. Voiding while standing is achieved.

Radial Forearm Free Flap Phalloplasty

In patients who desire a larger phallus, many different surgical techniques were reported using available local vascularized tissues or microvascular tissue transfers. The most widely used flap for total neophalloplasty is the radial forearm flap [13-17]. However, it has many drawbacks, e.g., an unsightly donor site scar, very frequent urethral complications, and a small penis that does not allow for a safe insertion of penile prosthesis in the majority of cases.

In the classic surgical procedure, three surgical teams operate at the same time: 1) the vascular surgeon prepares recipient blood vessels, 2) the urologist is operating in perineal area and prepares recipient site for neophallus, and 3) plastic/genital surgeon is dissecting the free vascularized flap of the forearm for tubularization and creation of the neophallus. Neophallus is transferred to the pubic area and fixed at the proper position. The radial artery is microscurgically connected to the common femoral artery in an end to side fashion. The venous anastomosis is performed between cephalic vein and the greater saphenous vein. One forearm nerve is connected to the ilioinguinal nerve for tactile sensation and another nerve is anastomosed to the dorsal clitoral nerve for erogenous sensation. The defect of the donor area is covered either by full-thickness or split-thickness skin grafts [18, 19].

Musculocutaneous Latissimus Dorsi Free Flap Phalloplasty

Since genitals have an important role in creating body image and, without any doubt, determine future mental image, we assumed that phalloplasty with normal-looking external genitalia and physical plays a main role in female to male gender reassignment surgery. This was the main reason behind our development of a new technique using the musculocutaneous latissimus dorsi free transfer flap, based on favorable experimental and clinical experience. It has a reliable and suitable anatomy to meet the esthetic and functional needs for phallic

reconstruction. Due to its workable size, ease of identification, long neurovascular pedicle and minimal functional loss after removal, the latissimus dorsi flap has been used for a variety of reconstructions.[20-24]. The main advantage of this flap is its large surface area, allowing for an excellent penile size (length and circumference), large enough to allow urethroplasty and implantation of a penile prosthesis. Moreover, the penis can be constructed to the size desired by the patient. Neophallus retraction seems less likely with muscle-based grafts than with fasciocutaneous forearm flaps, since denervated well-vascularized muscle is less prone to contraction than connective tissue. Sexual function of this neophallus remains problematic, as the flap lacks orgasmic sensitivity; it is restricted to the glans with a preserved dorsal nerve bundle incorporated at the base of the neophallus. Strong motivation and excellent cooperation of the partner are mandatory for a successful sexual intercourse [22, 23].

Figure 5. Design of the latissimus dorsi musculocutaneous flap.

A latissimus dorsi musculocutaneous flap of the non-dominant side is designed and harvested with thoracodorsal artery, vein and nerve. The surface of the flap is templated in two parts: 1) a rectangular part for neophallic shaft to be approximately 15X14cm and 2) additional, circular or semilunar component for glans reconstruction (Figure 5). The flap is completely elevated except for the neurovascular bundle, which was not transected until the recipient vessels and nerve had been prepared for microanastomosis. The neophallus is created while the flap is still perfusing on its vascular pedicle; the flap is tubularized in the midline and the neoglans formed by folding over and approximating to the penile shaft. The new constructed phallus is detached from the axilla after clamping dividing neurovascular pedicle with aim to achieve maximal pedicle length. The donor site defect is closed by direct skin approximation. If it is impossible, remaining donor site defect is grafted with split-thickness skin graft. Simultaneously, another team dissects the recipient area together with femoral artery, saphenous vein and ilioinguinal nerve. Additional “Y” incision is made in the pubic area and a wide tunnel is created to place the flap pedicle. The neophallus is transferred to the recipient area and microsurgical anastomoses are created between thoracodorsal and femoral artery, thoracodorsal and saphenous vein and thoracodorsal and ilioinguinal nerve (Figure 6). Specially constructed dressing is used to keep the neophallus in an elevated position for approximately 2 weeks.

Figure 6. Neophallus is created and fixed at the proper space above the new created scrotum. Microvascular anastomosis between neophallus and recipient blood vessels is done.

Figure 7. Neourethra is created from all available vascularized hairless tissue: urethral plate, labia minora and clitoral skin. Scrotum is formed by joining of both labia maiora. Perineum is fashioned as in male.

The principles of the reconstruction of the neophallus urethra are previously described [25-27]. In female-to-male transsexuals gap between the neourethra and female urethral meatus is always more than 10 cm. The principle of the reconstruction is the same as in metoidioplasty. Recently, we started to use all available vascularized hairless tissue to lengthen the neourethra maximally preventing the postoperative complications (Figure 7). For this reason, both labia minora and available clitoral skin are used for urethral tubularization. This way, new urethral opening is placed in first half of neophallus, minimizing the requests for longer neophallus urethroplasty. Further reconstruction is based on two-staged procedure. This principle introduced by Johanson in the 1950 is still in use today, directly or indirectly [28]. The first stage includes creation of the new "urethral plate" using buccal mucosa graft. Buccal mucosa grafts (either pairs or single, depending on the

width and length of neourethra needed) are placed on the ventral side of the penis. When the healed grafts are ready for final stage tubularization and closure, it is important to incise the underlying tissue that will support the neourethra and avoid ischemia at the neourethral suture line. It is recommended to create second layer from surrounding tissue to cover and support the new created urethra. The key for successful repair is waiting long enough until the skin is supple. Second stage should be performed when the “urethral plate” has matured enough to be supple and thus more easily mobilized for a tubularization. If it is necessary, additional buccal mucosa grafts can be used for urethral plate augmentation and easier tubularization.

ERECTILE FUNCTION

Erectile function in male transgenders is based on erogenous sensitivity and possibility to achieve erection. In transgenders who underwent metoidioplasty, erogenous sensation is fully preserved while the erectile size of the reconstructed clitoris is not enough for penetration. [29] In patients with total phalloplasty, erectile dysfunction is occurred due to the lack of erectile tissue and penile prosthesis implantation presents a suitable option. Its usage has frequently been associated with complications, sometimes in as many as 50% of cases [30].

The penile prosthesis is recognized as a most effective option to obtain an artificial erection satisfactory for sexual intercourse with penetration. These devices are subject to continuous development and they are achieving even better mechanical reliability and safety. Despite the fact that the penile prosthesis surgery represents the gold standard in patients with erectile dysfunction, they are also used to obtain rigidity in cases of phalloplasty performed for gender dysphoria [31].

Two types of penile prostheses, semi-rigid and inflatable, are usually used after total phalloplasty. The semi-rigid (malleable and mechanical) prostheses are characterized by two silicone cylinders and an internal twisted stainless steel wire core. Simple surgical procedure and easy usage present the main advantages. These devices have the disadvantage that the neophallus is always erect. However, it can be oriented in different ways depending on the need to urinate, to have sexual intercourse or to cover it with clothes. Inflatable prostheses may have two or three components. Two-component prostheses are composed of two flexible cylinders with a reservoir at the base connected to the pump. In three-component prostheses, reservoir is inserted in Rezius space or into the peritoneum and connected with pump and cylinders. The main advantages are that they feel softer than semi-rigid with better esthetical appearance and possibility to ensure more natural erection. The disadvantages are the possibility of malfunction and more postoperative complications (infection, erosion, etc.) [32, 33].

Only two surgical approaches, the infrapubic or/and the penoscrotal, are suitable for penile prosthesis implantation into the neophallus [34]. A longitudinal or a transverse incision is made below the pubis, just above the base of the neophallus. Hegar dilators are used to create the space for insertion of the prosthesis (Figure 8). The prosthesis is covered with vascular grafts imitating tunica albuginea to prevent protrusion through the glans. The prosthesis is additionally fixed to the periostium of the inferior pubic rami. Disadvantages of the infrapubic approach include possible damage of the neurovascular bundle of the neophallus and limited exposure for prosthesis insertion. Also, it is impossible to transfer the

tubes between cylinders and the pump located in the scrotum. The pump of the inflatable prosthesis is inserted into the scrotum using a small incision above the scrotum (Figures 9 and 10).

Figure 8. Second stage: dorsal approach is used for insertion of penile implants. Hegar dilators are used for creation of the proper spaces for cylinders.

Figure 9. Three-component inflatable prosthesis is inserted: both cylinders into the neophallus, pump into the left hemiscrotum and reservoir retrovesically.

With the penoscrotal approach, a vertical or a transverse incision is made ventrally at the penoscrotal junction. Initially, there was concern that this approach might be associated with a higher infection rate than the infrapubic approach, however, it has been shown not to be the case. Advantages of the penoscrotal approach include avoidance of injury of vascular supply, better exposure for prosthesis insertion, insertion of the pump without an additional incision and the ability to anchor the prosthesis to the pubic bones. Fixation of the cylinder bases to

the periostium of the inferior pubic rami stabilizes the prosthesis and discourages cylinder protrusion through the neoglans. With the vertical penoscrotal approach, all layers are opened longitudinally allowing good visualization of all structures, especially the urethra. The scar produced by this incision is barely visible and hidden between two hemiscrotums [35].

Figure 10. Appearance after closure of all incisions.

For a long time, conventional wisdom has dictated that if penile prosthesis revision surgery is necessary, it should be performed by the same approach that was used for the initial implant. When a patient presents for the explant of a semi-rigid prosthesis that was implanted via the infrapubic approach and reimplant of a three-piece inflatable prosthesis in its place, we go through the infrapubic scar and remove the malleable implants. The new prosthesis is then implanted using the described technique.

A major concern regarding erectile function in female to male transgenders is long-term follow-up. However, only a few reports with small numbers of patients have been published. Puckett and Montie firstly reported implantation of hydraulic prostheses after phalloplasty [36]. In two separated studies, Levine and Jordan reported low success rate in 4 and 8 cases, respectively [37, 30]. Two largest series of penile prostheses in male transgenders were published by Ghent group in 2003 and 2010 [38, 39]. Hoebeke et al, in the larger series to date, reported long-term follow-up in 129 patients who underwent female to male surgery. Inflatable prostheses were used in all cases with average follow up of 44.3 months. Since their data was only available on this subject, they compared results with studies on the subject of prosthesis implantation in males with erectile dysfunction and found some differences. First, higher risk of malposition in transsexuals is occurred due to missing of crura of corpora cavernosa. Second, tissue of the neophallus is totally different from natural cavernosal tissue and tunica albuginea and makes higher risk for protrusion and infections. Third, female to male transsexuals are usually younger and sexually more active than older males with erectile dysfunction. This fact may lead in more mechanical failures of prostheses.

CONCLUSION

Erectile function in female to male transsexuals is limited after phalloplasty. Metoidioplasty presents a good variant for patients who are interested to have small phallus with possibility to void while standing. They should be informed that the sexual intercourse will not be possible. However, it is always possible to perform some of regular procedures for total phalloplasty at a later stage, and with less risk of complications and operation time.

In total phalloplasty, insertion of penile prosthesis is required for penetrating sexual intercourse. In the past, attempts have been made to use part of bone or cartilage, but without satisfactory long-term results. Recently, two different models of penile implants are available, semi-rigid and inflatable. These prostheses are subject to continuous development and they are achieving ever better mechanical reliability and safety. Despite these high complication rates, penile prostheses implantation remains the best option for sexual intercourse after phalloplasty in female to male transgenders.

Keywords: failed back surgery syndrome; spinal cord stimulation; back pain; radiculopathy

INTRODUCTION

Spinal cord stimulation (SCS) continues to aid in the successful treatment of chronic pain conditions, namely those that are neuropathic in nature. There is no more common chronic pain ailment than back pain. A 2007 U.S. survey found that upwards of 17% of patients had experienced primarily lower back pain over the previous 3 months, roughly 34 million people [3]. It has long been questioned if back surgery is beneficial for these patients. Surgical interventions can be geared towards decompression, discectomy, laminectomy, or limiting painful vertebral movement with fusions or interbody cages. In 2001, hospitalizations for lumbar surgery totaled 356,638. Of those, over 122,000 were lumbar fusions for degenerative conditions, a 220% increase from 10 years prior [6]. With no concrete indications for surgical intervention due to chronic back pain, patients often times undergo surgery and are left with continued pain.

Multiple studies suggest at best a 70-75% success rate in regards to reduction of Visual Analog Scale (VAS) pain scores at 4 weeks post lumbar fusion [28]. This correlates with surgical modalities outside of fusions as well. However, upwards of 1 out of 4 patients will still experience notable pain postoperatively and there is no clear data describing long-term outcomes. Unsurprisingly, this embarks serious healthcare costs as a result. A retrospective

review in 2010 of 111 patients who underwent single level discectomy for lumbar pain and radiculopathy showed that the 36 patients diagnosed with postoperative mechanical back pain were billed a total of \$547,655.00 for workup, conservative therapy and subsequent fusion [27].

Table 1. Factors leading to failed back surgery syndrome

Preoperative Factors
Improper selection criteria
Premorbid psychological risk factors
Litigation
Improper communication of goals
Unrealistic expectations
Intra-operative Factors
Misdiagnosis
Wrong spinal level
Inadequate decompression
Residual disc material
Improper screw placement
Fusion instability
Postoperative Factors
Stenosis (residual or new)
Epidural fibrosis
Herniated disc (residual or new)
Worsening degenerative disc

As the number of patients undergoing back surgery continues to grow so does the prospective number of patients suffering from continued pain. Failed back surgery syndrome (FBSS) has been described as persistent back pain that may or may not include pain radiating to the leg after one or more back surgeries. That definition has evolved to also include pain that may be *post-surgical* in onset and may be referred or radiating pain. The etiology of FBSS can be approached temporally as related to surgery: preoperative factors, intraoperative factors and postoperative factors (Table 1) [9].

Preoperative factors describe conditions that apply to patient selection for surgery and can be a significant contributing factor to poor post-surgical outcomes. These conditions can frequently be elucidated with effective communication. Use of psychometric tests like Minnesota Multiphasic Personality Inventory (MMPI) can help identify some of the more predictive personality traits associated with poor outcomes, such as hysteria, hypochondriasis, and depression [8]. Understanding patient motives or secondary gains associated with worker's compensation cases may also be predictive of poor outcomes. Management of postsurgical expectations also plays a great role; a decrease of 3 or more units in VAS is considered an extremely positive outcome [32].

Intraoperative factors involve circumstances such as correct surgical diagnosis, surgical approach or operative events. For example, although spinal canal stenosis can be most evident from herniated disc material, its excision may not result in alleviating neuropathic pain due to

undiagnosed ligamentum flavum hypertrophy. A cautious approach must also be taken in the immediate postoperative phase where pain, increased pain or new pain may require surgical evaluation. Complications such as improper screw placement or fusion instability may result in permanent neurologic injury if not diagnosed quickly.

Postoperative factors relate to events that take place shortly after surgery or slowly develop over time as a result of back surgery. Structural changes due to surgical manipulation are unavoidable. Epidural fibrosis, internal disc disruption or residual disc material are frequently cited causes of continued pain after back surgery. It is also likely that the degenerative changes that prompted surgical correction develop on the contralateral side years later.

Just as with any other disease or ailment, history and physical examination are the starting point for patient evaluation. FBSS is defined as persistent back pain that may or may not include pain radiating to the leg after one or more back surgeries; it is therefore necessary to rule out surgical complications. Nerve root damage, although rare, may present as a focal neurologic deficit or bowel and bladder incontinence. Other complications such as cerebrospinal fluid leak, infection, bleeding or operative level instability should also be considered. Initial diagnostic imaging should include a basic standing X-ray in both flexion and extension to evaluate alignment, stability or degeneration.

Table 2. Imaging modalities

X-ray
Bony structures, alignment, and stability
MRI- Modality of choice
Effective in diagnosing most etiologies
Image quality may be effected by artifact if surgical hardware present
Contrast-enhanced imaging may be required if previous surgery for HNP
CT Myelogram
Alternative to MRI if surgical hardware causes artifact
CT w/Multiplanar Reconstructions
Optimal in patients who have had previous fusion and/or pedicle screws
Discography
Evaluate discogenic pain
Diagnostic injections
Useful for confirming etiology, particularly if the physical examination and imaging modalities do not match

Most frequently employed advanced imaging for diagnostic purposes in FBSS is MRI. (Table 2) [9]. Many, but not all, etiologies of FBSS can be found on MRI: spinal stenosis, degenerative disc disease, inadequate nerve root decompression, facet joint arthropathy, fibrosis or arachnoiditis. Interventional testing can supply more specific testing such as epiduroscopy, which will describe the degree of epidural fibrosis, as well as diagnostic injections can aide in confirming or localizing the spinal level acting as the pain generator.

Studies have shown that the use of SCS improves pain, quality of life, functional capacity and patient overall satisfaction in treating neuropathic pain secondary to FBSS [13, 14]. However, as with most chronic back pain a conservative initial approach is warranted. Physical therapy and pharmacologic management are mainstays of conservative management. Commonly, patients who have undergone back surgery and who now present with FBSS have already attempted physical therapy and may be on an intensive medical regimen for their pain. A retrospective review of 50 patients who underwent surgical treatment for FBSS showed significant improvement in pain and function in only 66% of patients, suggesting a low success rate [10]. In these situations, minimally invasive interventional procedures driven at the likely etiology of FBSS are a good choice.

Based on history and physical exam, assessing if pain is radicular in nature versus axial/musculoskeletal aids in generating targets of treatment. Radicular pain may be secondary to inflammatory processes originating from herniated nucleus pulposus, annular tears or nerve compression. Epidural steroid injections treat radicular pain by interrupting the inflammatory cascade initiated by the production of arachidonic acid from cell membrane phospholipases. Interlaminar, transforaminal or caudal approaches have all been described; data thus far displays mixed conclusions to the exact duration of pain relief expected. In the case of FBSS, anatomical changes from surgical hardware or manipulation make exact needle placement at times challenging.

Axial pain may present in a number of different ways: sharp, dull, throbbing, constant or intermittent. It is confined to a local anatomical region and thus pain is non-radiating. Muscle strain or facet joint arthropathy are common causes of axial pain. Medial branch block and radiofrequency ablation achieve zygapophyseal joint denervation resulting in decreased sensation of pain.

Epidural fibrosis secondary to surgical manipulation and trauma can be the causative etiology in FBSS in upwards of 8-14% of cases [4]. An MRI may show evidence of fibrosis but not accurately describe the quality and severity, therefore epiduroscopy under direct visualization will aide in identifying the severity and location of fibrosis. Adhesiolysis with lidocaine, hypertonic saline, non-particulate betamethasone or a less conservative approach, endoscopic under direct visualization may give pain relief in patients who are seemingly unresponsive to epidural steroid injections.

INDICATIONS FOR SCS IMPLANTATION IN FBSS

Over the years, the indications for spinal cord stimulator implantation have increased in order to treat a variety of pathologies that cause chronic pain. These indications include but are not limited to FBSS, complex regional pain syndrome (CRPS), refractory angina pectoris, peripheral vascular disease, phantom limb pain, and spinal stenosis [3, 12]. The success of

SCS in each of these indications varies. In addition to the treatment options mentioned earlier in this chapter, the use of SCS for FBSS continues to evolve with the development of better-designed electrodes, improvements in surgical techniques, and most importantly, with the implementation of evidence-based trials in order to support this indication. FBSS is by far the most common indication for SCS, with FBSS patients making up 70% of the patients treated with SCS implantation [12].

Spinal cord stimulator implantation has historically been the last resort treatment of neuropathic pain, following pharmacotherapy, physical therapy, and interventional modalities. Once these modes of treatment have all been exhausted, a psychiatric history has been performed, and imaging (MRI, flexion/extension radiographs, CT myelogram) has not show any surgically correctable factors, the clinician must move towards exploring surgical options which include spinal cord stimulator implantation, intrathecal drug delivery system, or reoperation [5]. Patients with predominantly neuropathic radicular pain are better candidates for SCS, as relief of axial pain is usually considered a secondary benefit [2]. Patients with predominantly axial back pain, even with improved electrode coverage, may not necessarily report a positive response to spinal cord stimulator implantation [7]. Furthermore, when considering surgical options, SCS has been shown to be more effective, cost effective, and safer [12, 23, 33].

Prior to permanent implantation, the patient must first undergo a period of trial stimulation with an external generator and percutaneous leads. If the patient is unable to obtain >50% pain relief from the temporary leads, the patient is not considered a good candidate for SCS as temporary pain relief is the greatest predictor of a negative outcome [36]. If the patient is able to achieve >50% pain relief along with the several other criteria mentioned earlier, the patient is then thought to be a good candidate for SCS. After the risks are discussed with the patient, the stimulator can be implanted and its effectiveness can be determined.

As more evidenced based studies portray the benefits and positive outcomes in SCS patients, the challenge for clinicians has slowly shifted from deciding whether or not SCS is a safe and effective treatment for FBSS, to deciding which patient spinal cord stimulator implantation will be most effective in and how soon to reach that decision. Two randomized clinical trials, which will be more closely examined in the following section, have already demonstrated that patients implanted with SCS report better pain relief, than those treated with repeat surgery or conventional medical management (CMM) [13, 14, 24].

EVIDENCE BASED OUTCOMES FOR SCS

In the past SCS has been thought of as the last resort, mainly due to a lack of evidence illustrating its effectiveness over conventional medical management and other treatments, dangerous potential complications, and prohibitive cost of implantation and maintenance. More recently, a number of studies have been conducted in order to examine the clinical effectiveness of SCS in FBSS patients.

A systematic review conducted by Frey et al. in 2009, demonstrated that only 9 of 25 observational studies and 2 of 6 randomized controlled trials regarding SCS and FBSS met the authors' inclusion criteria (methodologic quality assessment of 50 or higher) [7]. From

these 11 studies, Frey et al. found that the 2 randomized clinical trials, and 8 of the 9 observational studies showed positive results for short- and long-term relief after spinal cord stimulator implantation [7]. In the lone observational study, which did not show positive results, only 48% of the 182 patients included experienced 50% or greater long-term relief after spinal cord stimulator implantation [15].

The first of the two randomized controlled trials discussed was conducted by North et al. in 2005 [24]. In two separate studies performed in 1991, North et al. had demonstrated better outcomes in patients treated with SCS than those treated with reoperation at 5 years [19, 20]. In the randomized controlled trial, 50 patients with FBSS characterized by radicular pain were randomized to a reoperation or SCS group and were followed for an average of 3 years. Among the 45 patients available follow-up, 9 of the 19 SCS patients (47%) compared with 3 of the 26 reoperation patients (12%) reported at least 50% pain relief ($P < 0.01$). Patients in the SCS group were also less likely to cross over ($P = 0.02$) than those in the reoperation group. The reoperation group also required increased amounts of opiate analgesics when compared to the SCS group ($P < 0.025$).

The second randomized controlled trial, The Prospective Randomized Controlled Multicenter Trial of the Effectiveness of Spinal Cord Stimulation (i.e., PROCESS) trial followed 100 patients with neuropathic radicular leg pain for 24 months [13, 14]. From the 214 patients initially assessed for the study, 100 were selected; 52 were randomized to the SCS group and 48 to the CMM group. At 6-months, the primary outcome of 50% leg pain relief was achieved in 24 patients (48%) from the SCS group and 4 patients (9%) from the CMM group ($p < 0.001$) [14]. In addition to the primary outcomes, Kumar et al., also reported that the SCS group experienced lower levels of leg and back pain, higher health-related quality of life on 7 of the 8 SF-36 dimensions, better function, and greater satisfaction with treatment ($p < / = 0.02$ for all secondary outcome analyses). Along with these primary and secondary outcomes, SCS implantation also led to decreased analgesic drug intake and non-drug therapy use [14]. At 24 months, 17 of the 46 patients (37%) originally in the SCS group and 1 of the 41 patients originally in the CMM group achieved primary outcome ($p = 0.003$) [13]. At the conclusion of the study, 34 of the 72 patients (47%) who received SCS as the final treatment achieved the primary outcome, while 1 of the 15 patients in the CMM group achieved the primary outcome ($p = 0.02$).

These two randomized controlled trials supported the clinical effectiveness of SCS in patients with predominantly radicular leg pain, over CMM and reoperation. More importantly, they were paramount in establishing that SCS is an effective treatment for patients with FBSS.

A number of more recent studies have also attempted to support the use of SCS in patients with FBSS characterized by both radicular leg and low back pain. In a prospective multicenter trial in Europe, Van Buyten et al. notably showed pain relief achieved without paresthesia by using high frequency stimulation [34]. Seventy-four percent of the patients treated with high frequency (up to 10kHz) waveforms reported greater than 50% lower back pain relief at 6 months. At long term follow-up of 24 months, patients reported significant reductions in back and leg pain, decreased opioid use, and improved sleep and function [1]. This study, although having its limitations in its lack of a control group, was important in developing a modality within SCS to treat lower back pain along with the radicular leg pain symptoms found in FBSS.

At the time of this publication, several other trials examining SCS for FBSS are being conducted. North et al. are conducting the EVIDENCE study, which is an international multicenter randomized controlled trial assessing both the effectiveness and cost-effectiveness of SCS (implanted with a rechargeable pulse generator) versus reoperation through a 3 year follow-up in FBSS patients [26]. Rigoard et al. initiated recruitment for the PROMISE study, an international multicenter randomized controlled trial, in January 2013. This study will recruit patients with FBSS and predominant low back pain to compare the clinical effectiveness of SCS and optimal medical management versus medical management alone [30].

SCS has also been shown to be a more cost-effective treatment modality than reoperation and CMM [23, 33]. Kumar et al. added that even failed-SCS is more cost-effective than CMM alone [12]. Kunal and Wilson further stated that an argument can be made to implant patients earlier in the patient-selection and operation algorithm, as many patients are unable to obtain positive outcomes after SCS due to the delay in treatment [17]. Several studies have been conducted regarding the relationship between delay in treatment and implantation success, and the causes behind it [12]. These cost-effectiveness and time-to-treatment studies will help further support the notion that SCS should not be considered a last resort treatment, instead, an effective treatment modality which should be considered earlier for the “right patient.” In order to further develop this treatment algorithm for FBSS patients, additional studies must strive to create a more precise picture of which patient SCS will be most effective in earlier along in the treatment selection process.

SPINAL CORD STIMULATOR LEAD PLACEMENT

Spinal cord stimulator technology has significantly progressed over the past decades as newer leads, pulse generators, and targets have emerged. In this section, we will briefly discuss lead placement as it pertains to FBSS.

As discussed earlier, percutaneous cylindrical leads have generally been used in trial stimulation, while a paddle lead is typically placed via laminectomy. Although percutaneous leads provided a less invasive approach for lead placement and can be done under local anesthesia, they have historically been associated with poor outcomes possibly due to high rates of lead migration [22, 29]. The often-referenced randomized control trial study by North et al. from 2005 demonstrated that laminectomy electrode placement produced better results than percutaneous placed electrodes in FBSS patients at a mean of 1.9 years follow-up, though this statistical significance was lost at 2.9 years of follow-up in their small sample size [22]. A study performed a few years prior by Villavicencio et al., also found better outcomes long-term in patients with laminectomy placed electrodes. These studies, along with lower reported rates of migration, less lead breakage, lower output parameters, and better results in FBSS patients strengthened the perception that implantation of plate type electrodes under direct vision via laminectomy was superior [16, 21, 25].

More recently, a number of studies regarding percutaneous-placed electrodes have shown equal or better long-term outcomes in FBSS patients [11, 18, 35]. These studies regarding percutaneous methods of implantation have demonstrated improved migration rates and patient satisfaction when compared with studies performed in the past. While these

percutaneous implantation methods can be sufficient in less complex cases, FBSS patients at times can present a much more complex problem requiring multicolumn lead placement. Rigoard et al., in a recent nonrandomized observational study, suggested the efficacy of multicolumn surgically implanted leads, and importantly noted the millions of potential programming combinations available to optimize stimulation [31]. These leads which include, Medtronic 5-6-5 and Penta, St. Jude Medical, may require a more stable spatial relationship among the multiple columns so that they can provide adequate coverage [12]. Both these leads are designed to improve lateral coverage, which may assist in treating axial back pain along with the radicular symptoms found in FBSS patients [30].

CONCLUSION

Failed back surgery syndrome represents one of the most common indications for spinal cord stimulation. Candidates must be carefully selected, and must have realistic treatment goals. In the well-selected patient, spinal cord stimulation has been shown to be safe, efficacious, and cost-effective. With advances in technology and surgical technique, patient satisfaction has been improving. Moving forward, long term outcomes studies and studies of functional outcome and return to work will be of importance.

Chapter 379

COMPLICATION AVOIDANCE AND REVISION SURGERY

***Sameah A. Haider, Meghan E. Wilock
and Julie G. Pilitsis*, MD, PhD***

Department of Neurosurgery, Albany Medical College, Albany, NY, US

ABSTRACT

Neuromodulation offers a reversible, low risk, and cost-effective treatment modality for select patients with chronic neuropathic pain refractory to conservative management and surgical approaches. While the indications for neuromodulation are broadening, spinal cord stimulation (SCS) for failed back surgery syndrome (FBSS) or complex regional pain syndrome (CRPS) remains the most well-established and most utilized modality of neuromodulation. Nearly four decades since its inception, the burgeoning arena of spinal cord stimulation (SCS) has been met with iterative advances in technique, technology, and efficacy. The authors describe the incidence, clinical manifestation, therapeutic approach, and avoidance of complications related to spinal cord stimulation. Understanding the complications of SCS is important not only for evaluating postoperative patients but also essential for avoiding therapy failure, advancing operative techniques, maximizing outcomes, and improving quality of life for patients.

Keywords: adverse events, complications, neuromodulation, spinal cord stimulation, chronic pain, hardware, biologic, biopsychosocial

INTRODUCTION

Since its advent in the late 1960s, spinal cord stimulation (SCS) has made considerable advances in the treatment of chronic pain refractory to conservative medical management or surgery. This modality has gained traction in recent decades, owing to its minimally-invasive

* Corresponding Author's Email: Pilitsj@mail.amc.edu.

nature, safety, efficacy, and reversibility [1]. Originally based on the gate control theory of pain [2], modern day SCS stemmed from the idea that electrical currents applied along the spinal cord could moderate pain perception by modulating small and large diameter afferent pain fibers [1, 3, 4]. Although the precise mechanism by which SCS exerts its therapeutic effects remains elusive, we now appreciate other pathways may be involved (i.e., supraspinal centers, neurotransmitters, autonomic nervous system) [4, 5, 6].

Candidates for SCS are screened on the basis of their underlying pathology, thereby reserving SCS for patients deemed to reap the greatest benefit. FDA-approved indications for SCS include chronic neuropathic pain of the trunk and limbs, failed back surgery syndrome (FBSS) and complex regional pain syndrome (CRPS) [7]. Literature to date suggests the best outcomes of SCS have been reported for FBSS, CRPS, refractory angina pectoris, and critical limb ischemia secondary to peripheral vascular disease [3, 6, 8].

SCS has long been plagued by a high complication rate—between 30-40% of patients report complications [3] while 23.1-34.3% require revision [9]. Although the rate is high, the majority of complications are relatively reversible without any permanent sequelae [10, 11]. SCS complications are predominately hardware-related, with lead migration, lead fracture, and need for lead repositioning representing the most common complications. While hardware-related complications typically occur within the first 2-years, biologic complications predominate within the first 3 postoperative months [3, 9].

We conducted a literature review using PubMed, Web of Science, and Google Scholar databases. Keywords used include “SCS”, “complications”, “adverse effects”, “allergy”, “foreign body”, “mental health”, “biopsychosocial”, and “psychological”. Applicable English sources were selected for retrieval with additional cross-reference search of cited literature. Our investigation of SCS-related complications is organized into distinct classifications: 1) hardware-related, 2) biologic, 3) stimulation-related, and 4) cognitive/behavioral considerations.

HARDWARE COMPLICATIONS

Lead Migration

Hardware-related issues comprise the majority of SCS-related complications, but adverse events have decreased substantially with evolving technology, technique, and device improvements seen in recent decades [1, 12]. The most frequent cause for surgical revision of SCS is lead migration [5, 13] (Figure 1). Occurring in 11.3-22.6% of patients treated, not only is lead migration the most common cause of revision but it is also the most common complication of SCS overall [3, 11, 12, 14, 15, 16]. When the electrodes shift from their original site of placement within the epidural space, the patient may experience 1) a change in paresthesia coverage, 2) acute changes in amplitude requirements to sustain the same level of coverage, 3) loss of pain control, or 4) other clinical manifestations [12]. Lead migration most commonly occurs within the first four weeks after implantation; after this period there is a greater degree of fibrosis. Anatomic location within the spinal canal is related to incidence of lead migration due to relative differences in mobility within the cervical, thoracic, and lumbar spines. Hence cervical and lumbar placements have greater migration rates than their thoracic

counterparts [3, 12, 16, 17]. Lead migration occurs more commonly in the axial plane (cephalocaudad direction), rather than transversely (laterally within the epidural space) [3, 5].

Figure 1a. Intraoperative anterior-posterior Xray of two octrode percutaneous leads spanning from mid C2 to the upper level of C4. 1b. Anterior-Posterior Xray demonstrating bilateral lead migration in the caudal direction. Patient presented with loss of therapeutic stimulation on her right side.

In recent decades, improvements in electrode design and surgical technique have lessened the burden of electrode migration. Over a period of 22 years and 410 patients, Kumar et al. noted a lead migration incidence of 21.5%-- however, when the latter decade of that study period was analyzed separately the incidence dropped down to 11.3% [16,18]. During this same period, there was also a decline in surgical revision rates [18] (Kumar et al. 2006a). The

use of more electrodes per paddle has allowed strategic reprogramming of the stimulation pattern along the spinal cord to appropriately recapture target areas when leads inappropriately migrate. A greater number of contacts on the leads promotes a greater degree of flexibility in reprogramming (Figure 2); ultimately this translates to a greater likelihood of reestablishing therapeutic paresthesia coverage [3, 12]. In one study the revision rate for bipolar leads was 23%, whereas the same was 16% in multichannel leads and 3.8% in octopolar leads [11, 16].

Lead Migration: Recommendations

Proper patient education regarding activity restrictions will help limit the occurrence of lead migration. Namely, patients should avoid excessive twisting, bending, and lifting during the first six weeks postoperatively [3,9]. If a patient has a prior history of lead migration or difficulties with placing percutaneous electrodes during trial, surgical placement of paddle

electrodes via laminotomy is preferred since long-term reoperation rates are lower for paddle electrodes [5, 6, 12].

Surgical approaches that may affect lead migration include appropriate use of anchoring techniques, anchoring points, and anchor types. Electrodes should be anchored to the fascia [3, 9]. The incorporation of strain-relief loops between the anchor and implantable pulse generator (IPG) provides slack and limits traction forces on the lead [9, 18]. Permanent implantation of percutaneous leads requires a suture between the supraspinous ligament and anchor with an additional suture between the anchor and fascia. The anchor/lead interface can be additionally secured using a silicone elastomer adhesive between the inner sleeve of the anchor and outer diameter of the passing lead [19, 20]. For paddle leads, anchors, when used, should be secured to the fascia with strain relief loops in the epifascial plane [9, 21, 22]. Additional strain relief is provided by coiling redundant loops of lead beneath the IPG [19]. For a more comprehensive account of anchoring mechanisms, please refer to the Neuromodulation Appropriateness Consensus Committee publication on Avoidance and Treatment of Complications of Neurostimulation [3].

In face of the clinical picture of lead migration, initial management should include repeat X-rays to compare the current location of electrodes to the post-implantation location [3]. Given most contemporary leads employ multichannel arrays; the best course of action is to attempt recapturing pain control through reprogramming. If alternative programming fails to correct the issue, a surgical revision is necessary [12].

The location of the IPG pocket also has a role in the tendency of lead displacement. Implantations in the gluteal area were associated with double the rate of lead migration when compared to those placed in abdominal pockets, 21% and 10% respectively. Implantation in the gluteal region, however, confers several advantages over IPG placement in the abdominal pocket; Scheepens et al. report a reduction in operative time, fewer incisions, lower infection rate, and decreased incidence of pain over the IPG site. Positioning the IPG in an abdominal pocket requires repositioning the patient from prone to lateral decubitus, as well as prepping and draping the patient once again [23].

Lead Fracture

The incidence of lead fracture ranges from 3-9.1% in the literature [11, 12, 13, 14, 16]. A recent account on the present state of neuromodulation by Kumar et al. supports the notion that the incidence of lead fracture is on the decline as a result of improved manufacturing methods [1]. One should suspect the possibility of lead fracture if there is a sudden decrease in pain relief, a loss of induced paresthesia, or a burning sensation [12]. Anchoring may play a role; when the nose of the anchor was pushed through, and circumferentially invested by, the deep fascia the cylindrical electrode was able to withstand 200,000 bend cycles before failure. When the anchor was located a distance of 1cm or greater from the lead exit-point the electrode only withstood 5,500 bend cycles until failure [16].

Lead Fracture: Recommendations

Methods used to reduce the risk of lead migration are similarly employed to decrease the likelihood of fracture. For instance, appropriate anchoring techniques, use of strain-relief loops, and consideration of IPG locations [12]. Initial management of suspected fractures involves x-ray of the entire SCS system and an impedance check.

Abnormal impedance values are reflective of an open circuit and will require replacement of the broken lead(s) [12, 18].

Miscellaneous Hardware Complications

Implantable pulse generators are either rechargeable or nonrechargeable [12]. The operational lifespan of a battery is dependent on the usage characteristics of the SCS system. Patients that require stimulation at greater amplitudes, higher pulse widths, and for longer durations of stimulation have a shortened battery life [9]. Additionally, the characteristics of the leads used also impact energy consumption. For instance, when compared to paddle electrodes, cylindrical percutaneous electrodes are less efficient due to their higher impedances and radially-directed energy dispersion [12].

The complication of unexpected battery failure occurs when an IPG battery requires replacement before the estimated date—the expected date of depletion is approximated using the patient-specific usage characteristics [3]. The incidence of unexpected battery failure was reported as 1.6% in a meta-analysis by Cameron and 1.5% in a retrospective analysis by Kumar et al. [11, 18]. If a patient is expected to be a high-energy utilizer of the IPG or if the battery is estimated to last less than 4.25 years, then a rechargeable IPG unit is recommended [9, 17]. With the aforementioned scenario, the patient is spared from lapses in SCS performance, reoperation for new battery placement, and the rechargeable unit becomes the more cost-effective alternative [17].

Device interference is a concern when considering the use of MRI in patients with older SCS. Complications include infarct, paresthesia, pain, and complete dysfunction of the SCS apparatus [5]. In a case report by Simopoulos and Gill, the authors recount the experience of a 50-year old patient with thoracic SCS who underwent lumbar MRI; the SCS apparatus was turned off prior to the imaging study. During the MRI, the patient experienced a sensation of heat from the IPG pocket and multiple jolting dysesthesias along his back. Any future attempts to turn the SCS back on resulted in similar sensations, despite unaffected paresthesia coverage. Radiography, reprogramming, and interrogation of the system did not yield any abnormalities or improvements. The patient required surgical revision with replacement of the IPG and subsequently returned to baseline at follow-up [24]. There are a number of indications for which MRI is considered the benchmark for diagnosis and surveillance; thus the inability to utilize this modality is a point that must be discussed with patients prior to implantation. Recently, a new device has been FDA approved for use with full-body MRI, up to 1.5T. [3, 5, 25].

BIOLOGIC COMPLICATIONS

Infection

The possibility of infection is an inherent risk associated with any surgical procedure. This complication can be particularly costly in the setting of SCS; an infection that fails to resolve with conservative treatment often necessitates reoperation and explantation of the hardware (Figure 3). The incidence of infection in SCS ranges from 3.4-4.6%, commensurate with surgical-site infection (SSI) rates for spine surgery overall [3, 5, 10, 11, 12, 14, 18]. The three main presentations of infection include superficial SSI, deep SSI, and abscess formation [3]. With the latter two presentations being exceedingly rare, the risk of life threatening infection and permanent sequelae is outstandingly low. In a retrospective series of 707 cases with an infection rate of 4.5%, all infections resolved with antibiotics alone and produced no permanent morbidity [14]. In our experience, we have been able to treat a number of superficial issues with antibiotics alone. When this was not possible, we removed some or all of the hardware. A systematic review of complications among 21 SCS studies suggested that the rate of SSIs was 4.5% for superficial SSI and 0.1% for deep SSI—the former usually occurred within 30 days while the latter is conceivable up to 1 year post-implantation [3, 15]. The literature to date reports only one case of death due to infection and one case of paralysis secondary to epidural abscess [9, 11, 12]. The most commonly cultured organisms are staphylococcus aureus and staphylococcus epidermidis [3].

Figure 3. White arrow denotes vesicular outpouching of skin due to indolent infection with staphylococcus epidermidis. Surrounding pigmented area depicts an old tattoo.

Infection: Recommendations

Prevention of surgical site infections in neurosurgery is a well characterized topic hence our discussion will be limited to recommendations specific to SCS. With respect to the trial period of stimulation, there appears to be a positive association between trial length and risk of infection [12]. In the interest of decreasing the infection incidence, the authors suggest judicious choice of trial length [12].

Given the potential morbidity associated with infection and the costly nature of surgical explantation, vigilance for postoperative signs of infection is of utmost prudence. The clinician should initiate the appropriate work up for infectious etiologies should clinical symptoms of wound infection present; this includes, and is not limited to, complete blood count, culture specimens from the surgical site and implant site, blood cultures, erythrocyte sedimentation rate, C-reactive protein, and contrasted computed tomography scan. Empiric antibiotics should be promptly initiated after a culture is taken with appropriate amendments once culture and sensitivities return. During conservative management of a SSI, one must be watchful for signs of advancing infection, deeper infection, or neurologic involvement. Surgical revision with removal of the device is then required. Explant is also indicated if the infection is in close proximity to hardware; in most instances this is limited to the IPG and extension wire with sparing of the epidural constituents [3, 12].

Pain at IPG Site

Postoperative pain at the IPG implantation pocket may be disconcerting to patients; however, the pain is typically transient in nature and resolves within 7-14 days. The pivotal PROCESS study by Kumar et al. demonstrated a 12% incidence (5 of 42 patients) of pain at the IPG site [26] with a similar incidence of 10% demonstrated in our series (unpublished data). In a larger sample of patients from 1995-2004 from the same authors, the incidence of discomfort over the IPG dropped down to 2.5% [18]. Later studies with larger sample sizes reported zero cases pain related to device components [14,19] while a meta-analysis of the literature reported a 0.9% incidence. Of note, it is speculated that the abnormally high incidence of pain over device components observed during the PROCESS trial may be attributable to the larger size of IPGs utilized [3].

Pain at IPG Site: Recommendations

Discomfort related to the site of device components is a transient symptom that is nonetheless a true nuisance to the patient; it is best managed with empathy and reassurance. Although reductions in device size may have helped decrease the incidence of this complication, the implanter may additionally reduce this occurrence by avoiding placement of the IPG pocket in close proximity to the ribcage or inguinal ligament [18]. Local pain may be an early sign of infection or burning discomfort can be indicative of a damaged connection with the extension wire [12]. At our center we often employ a local injection of triamcinolone and lidocaine. With the injection and/or lidocaine patches, we offer to move the battery. If an electrical leak is suspected, the battery is replaced. By choosing a lead of appropriate length,

we may avoid the use of an extension wire and directly connect lead to IPG—this technique minimizes the number of components and reduces potential failure modes.

CSF Leak and Dural Puncture

CSF leak is an iatrogenic complication that infrequently occurs after percutaneous lead placement (incidence 0–0.3%) and surgical paddle lead placement (incidence 0.05%) [3]. Levy and colleagues similarly report that dural puncture is more common with percutaneous electrodes (0.3%) than with paddle electrodes (0.2%) [10]. The clinical presentation includes positional headaches, neck pain, hearing loss, tinnitus, diplopia, and/or vertigo occurring 1–3 days postoperatively. Risk factors include anatomic changes that make technique or visualization more onerous, such as: calcified ligamentum flavum, spinal stenosis, or previous surgery/puncture at the needle entry point [3].

CSF Leak and Dural Puncture: Recommendations

The clinical manifestation of PDPH within the first few postoperative days should increase suspicion of a CSF leak. The incision sites must be examined for evidence of clear fluid seepage. Conservative management includes several days of flat bedrest, use of abdominal binder, caffeine, and/or butalbital/acetaminophen/caffeine combination pill [12]. If symptoms are severe or conservative management fails, an autologous blood patch or saline can be employed into the epidural space [12, 18]. While evidence suggests that epidural blood patch should be offered within 24–48 hours of dural puncture [27], the literature also describes successful use within five days [28]. During application of the epidural blood patch, the use of fluoroscopy and a slow infusion rate is instrumental in avoiding manipulation of the epidural electrodes [28]. As the mechanism of action of a blood patch is thought to be a compressive one, injecting preservative free saline is another option if autologous blood is not readily available [27, 29].

An intraoperative dural puncture may become evident when CSF is visible in the surgical field. While some surgeons may choose to continue lead placement at the same level or a different level, others recommend aborting the SCS trial/implantation attempt, placing an autologous blood patch, and rescheduling the procedure in 3 weeks at minimum [3, 12, 18].

Subcutaneous Hematoma and Seroma

A collection of blood or serous fluid beneath the skin, most commonly located at the IPG site, may develop within the weeks following surgery. This complication may occur when dead space is left [3]. The reported incidence in the literature ranges from 0–9%; a series of 160 consecutive SCS patients presented a 3.1% incidence [18]. Patients may present with swelling, redness, or pain at the site therefore infectious etiologies often need to be ruled out. Risk factors for hematoma/seroma development include smoking, diabetes, and patients with poor wound healing [3].

Subcutaneous Hematoma and Seroma: Recommendations

The majority of seromas resolve spontaneously and expeditiously if not infected. We only recommend aspiration and compression with a dressing/binder if there is a high concern for infection [12]. The Neuromodulation Appropriateness Consensus Committee recommends several techniques to minimize the risk of hematoma/seroma formation: minimal cautery, meticulous attention to hemostasis, layered closure, and gentle pressure via the use of an abdominal binder [3, 10]. Additionally, creating an IPG pocket that is as small as possible further decreases the likelihood of seroma formation [12].

Symptomatic Epidural Hematoma

Bleeding in the epidural space, with or without expansion of a developing clot, is recognized as an epidural hematoma. The source of bleeding is usually within the epidural space itself, though it may be from paraspinal vasculature. Although exceedingly rare, a symptomatic epidural hematoma (EDH) is a feared complication due to its potential for cord compression and permanent neurological deficit [10]. An EDH generally presents within the first 24 hours, though this time frame may be longer in patients restarting blood thinners. A systematic review of 2,972 cases revealed no occurrences while a separate series of 2,000 patients revealed two occurrences of EDH [12]. In a meta-analysis of 68 studies spanning 20 years of data, Cameron reports the incidence to be 0.3% with the incidence of secondary paralysis as 0.03% [11].

Using the FDA MAUDE (Manufacturer and User Facility Device Experience) database of 44,587 SCS patients, Levy et al. report the incidence of epidural hematoma to be 0.19% (83 cases). Of the 83 cases, 68 experienced some degree of motor deficit. Intrinsic limitations of the MAUDE data set make it difficult to extrapolate a true rate of recovery for patients who suffered from EDH [10].

While the preoperative evaluation may uncover coagulopathies, it is important to note that platelet dysfunction due to aspirin and/or newer anti-coagulants use may go undetected. It is thus prudent to advise patients to avoid all blood thinners, fish oil, vitamin E, aspirin and aspirin containing products (i.e., popular over-the-counter headache remedies containing acetaminophen, aspirin, and caffeine) 7 days before and up to 7 days after operation. Exact recommendations should be made by the surgeon and the doctor prescribing the anti-coagulant.

Symptomatic Epidural Hematomas: Recommendations

Operative techniques to minimize the risk of EDH include the use of: 1) meticulous attention to hemostasis, 2) hemostatic agents such as bone wax, Gelfoam, thrombin, Flo-seal, etc., and 3) multi-layered closure. As with other spinal procedures, the routine use of a drain is not recommended due to increased risk of infection [10, 12].

Any SCS patient that develops progressive motor, sensory, or autonomic deficits at the commencement of postoperative recovery should be evaluated for an epidural hematoma with

an urgent noncontrast CT [3]. Symptomatic epidural hematomas, regardless of size, should be surgically evacuated due to risk of permanent neurological damage.

Direct Neuraxial Injury

The early pioneers of neuromodulation encountered greater morbidity and adverse neurological outcomes than currently experienced. Over the past 4 decades, evolving technology, technique, and understanding have made permanent neurologic sequelae the rare exception [10,30,31]. Prior to 1980, SCS was achieved using subdural and intradural electrodes; this approach of ‘dorsal column stimulation’ was inherently riskier than later approaches that did not violate the dura [5].

In a 1967 series of 90 patients undergoing dorsal column stimulation (DCS), 6 out of 90 patients experienced paraparesis or paraplegia [10]. A subsequent analysis of DCS in 1978 reported delayed paraparesis in 2 out of 92 implants [30]. A 2010 analysis of 44,587 cases yielded a considerably lower rate of neurologic injury; 0.13% of patients experienced major motor deficit without epidural hematoma and 0.10% experienced limited motor deficit without epidural hematoma. The presence of postoperative motor deficit in the absence of epidural hematoma was inferred to be a result of direct spinal cord injury [10], however, transient cord ischemia or vasospasm are also possible.

To decrease the risk of spinal cord injury, preoperative imaging is mandatory as it may reveal evidence of spinal stenosis, spondylosis, disc herniation, vascular anomalies, or general anatomic morphology for operative planning. Spinal stenosis is not an absolute contraindication to SCS, granted there is adequate decompression prior to implantation [10].

In a recent series of 172 patients undergoing paddle-electrode SCS, 8.7% of patients suffered new-onset thoracic radiculopathy that was refractory to medical and conservative management. Surgical revision with a more extensive laminectomy or dorsal decompression produced immediate resolution of symptoms [32]. In our experience, we have been able to place a smaller lead in revisions of these cases to maintain the therapy but relieve the radiculopathy.

Miscellaneous Biologic Complications

Despite the reported biocompatibility of SCS devices, several case reports have described allergic reactions attributable to device components. Contact dermatitis is a local T-cell mediated delayed-hypersensitivity reaction in response to immunogenic antigens. Device constituents/components that been implicated in the development of hypersensitivity reactions include: silicone, polyurethane, titanium, platinum, iridium, nickel, and epoxy [33, 34, 35]. The patient with an allergy to device components typically presents within 8-days to 1-month, although a delayed hypersensitivity is conceivable several months after implant. Symptoms include rash with or without pain, erythema, pruritus, or delayed wound healing [33, 34, 35].

Although a very rare occurrence, appreciating the clinical presentation of a local immunologic reaction and including it in the differential diagnosis of cutaneous inflammation may help avoid unnecessary device removal. Upon suspicion of an allergic reaction, it

remains prudent to rule out infectious etiologies with tissue cultures or biopsy. Features that make infection less likely include 1) a well demarcated, non-advancing area of inflammation, 2) absence of fever, 3) absence of purulence.

Initial workup should include cutaneous patch testing of the various allergens that may be responsible—a model-specific patch testing kit may be available directly from the device manufacturer [34,36]. A negative patch test does not exclude the possibility of allergic reactivity, thus excision with histological analysis may be required [33]. A trial of topical steroids may be employed; however, we caution that there exists at least one reported case where this modality may have contributed to poor wound healing and dehiscence [33, 35]. While management generally calls for removal of the device [11, 33, 37], Gadgil and colleagues report successfully treating IPG-related contact dermatitis by encasing the device in an expandable polytetrafluoroethylene (ePTFE) sheath and reimplanting it within the subcutaneous pocket [34].

A foreign body reaction is a non-allergic, inflammatory process that may present similarly to allergic contact dermatitis, however, may take months or years to develop. A foreign body reaction occurs due to the body's persistent efforts, and failure, to remove non-self-particles. Failure to digest the foreign particles results in the body's attempt to wall-off the offending area with granuloma formation. Diagnosis is made histologically, with the presence of fused-macrophages—so called 'giant cells' [33]. A review of the literature uncovers three case reports of foreign body reactions occurring at the site of epidural electrode placement. All three presentations resulted in compression of the spinal cord with symptomatic resolution status-post surgical removal and lysis of epidural adhesions [38, 39, 40]. We recommend that foreign body reaction be included in the differential for etiologies of late-onset cord compression.

The complication of skin erosion in areas overlying hardware is a rare event (0.2% incidence) [11]. Skin erosion increases the risk of infection, epidural abscess, and wound dehiscence. Appropriate measures to help limit this complication include a) multi-layered closure, 2) avoiding placement of suture lines directly over the implanted device, 3) and implanting the IPG away from bony elements. Any presentation of skin erosion should include an appropriate workup for superimposed infection [3].

STIMULATION-RELATED COMPLICATIONS

Positional Dependence

The thickness of the dorsal CSF layer varies between patients and makes the greatest contribution to the overall distance between electrode and spinal cord. In addition, the dorsal CSF layer is the most variable constituent with a degree of thickness that is dependent on a) spinal level, b) body position/posture, and c) spinal canal morphology [5, 11, 41, 42]. While the SCS electrode is relatively fixed in position within the epidural space, the spinal cord is mobile.

With a fixed intensity of electrical stimulation, changes in thickness of the dorsal CSF layer contribute to understimulation and overstimulation [42]. In the supine position the spinal cord is shifted dorsally with a dorsal CSF layer of 2.0-6.0mm at T11. In the prone

position the spinal cord is shifted ventrally, increasing the dorsal CSF layer by approximately 2.2mm [42]. It becomes no surprise that the supine position, with a smaller electrode-to-spinal cord distance, results in overstimulation of target spinal tissue. Conversely, the prone position, with a larger dorsal CSF layer, is associated with subtherapeutic paresthesia [5]. While understimulation is associated with decreased paresthesia and a reduction in pain relief, overstimulation has been described as a dysesthesia of uncomfortable jolts, surges, and pain [3, 42].

Positional Dependence: Recommendations

SCS systems include a handheld programmer for the patient to manually adjust stimulation settings on an as-needed basis. Nonetheless, patients may find that changing stimulation parameters throughout the day is inconvenient and unnecessarily repetitive. Over and understimulation induced by positional changes can disrupt pain relief and cause frustration, worsening health-related quality of life. Additionally, the need to frequently reprogram a SCS with position changes imposes a gratuitous burden on patients and may contribute to therapy failure and dissatisfaction.

The problem of positional dependence has compelled the development of SCS devices with built-in position-sensing capabilities. Sensor-driven devices embrace integrated accelerometers to detect positional changes and automatically adjust stimulation intensity to individually-preset parameters. The use of this novel SCS in a multicenter, randomized, open-label trial with 15 patients revealed improved patient satisfaction with automatic sensor-driven stimulators versus manually adjustable stimulators with respect to position changes and physical activity [43]. A larger prospective, randomized crossover study with 79 patients reported comparable positive outcomes: 1) 86.5% experienced improved pain relief with no loss of convenience or no loss of pain relief with improved convenience, 2) 80.3% improved comfort during position changes, 3) 69% improved physical activity, and 4) 47.9% improved sleep [42]. The position-sensing SCS group and the manually-adjustable SCS group showed no statistical difference with respect to incidence of adverse events and unpleasant sensations. In addition, 90.1% of patients wished to keep the sensor-driven SCS in the automated mode all, or most, of the time [42]. In a prospective cohort of 62 patients at the authors' home institution, patients with position-adaptive devices achieved greater reductions in VAS scores at short-term follow-up than their counterparts fitted with standard devices [44].

Aberrant Stimulation: Autonomic Dysfunction

A handful of reports depict variable manifestations of gastrointestinal symptoms after SCS implantation. The precise mechanism by which SCS affects gastrointestinal function is unclear; current hypotheses postulate induced imbalances between sympathetic and parasympathetic tone [3, 45, 46, 47]. La Grua describes an occasion in which thoracic SCS for FBSS produced persistent constipation, distension, and abdominal pain refractory to pharmacologic treatment. Subtherapeutic levels, or complete cessation, of stimulation resulted in symptomatic alleviation or resolution, respectively [46]. A similar effect of decreased intestinal motility was observed as an unintended side effect in a patient treated with thoracic

SCS for refractory pain secondary to IBS; the frequency of diarrheal episodes was dramatically reduced from multiple daily episodes to less than once a month [48]. Thakkar et al. describe two patients who suffered persistent nausea, vomiting, diarrhea, and worsening reflux after SCS; the first patient with CRPSII became symptomatic during multiple SCS trials while the second patient with FBSS achieved a successful trial and developed symptoms immediately after permanent implantation of the device [3, 49]. Symptoms did not resolve despite efforts to reprogram stimulation parameters and both patients inevitably required device removal [49]. Gastrointestinal side effects of SCS are not uniformly predictable; however, they appear to be refractory to medical management and reversible upon cessation of stimulation.

Case reports of urologic dysfunction after SCS include urethral sphincter spasm, urge incontinence, and micturition inhibition. In a patient with spinal cord injury at T12-L1, thoracic SCS for neuropathic pain resulted in urethral sphincter spasm that impeded successful self-catheterization [3]. La Grua and Michelagnoli report of a patient with pre-existing T11-L1 spinal cord injury, secondary to cord compression from an angioma, who underwent thoracic SCS with resolution of neuropathic pain but new onset micturition inhibition [50]. Although urologic complications appear to be a rare, reversible occurrence, it may prove beneficial to perform urologic function testing during the SCS trial period for patients with a history of spinal cord injury or genitourinary pathology [3].

Stimulation Tolerance

The phenomenon of stimulation tolerance is best described as the gradual loss of therapeutic pain relief or the increase in stimulation requirements to achieve the same level of analgesia [3, 16]. Stimulation tolerance occurs in the absence of hardware-related complications, as evidenced by an unchanging paresthesia distribution overlying painful areas. Theorized etiologies include: neuroplasticity (local or supraspinal pathways), disease progression, or psychological factors. Autopsy and surgical inspection fail to support the theory of peri-electrode fibrosis as a potential mechanism of stimulation tolerance [16].

Several studies have suggested that SCS becomes less efficacious after a period of 2-3 years; reported incidence of stimulation tolerance varies from 21-30% [3, 15, 16]. Despite a trend towards gradually diminishing efficacy with time, studies to date nearly unanimously report patient willingness to undergo SCS again [15, 51, 52, 53]. Thus, patient inclination to repeat SCS in order to achieve identical results is a testament to the perceived benefit provided by treatment. The intrinsic purpose of SCS is not the complete elimination of pain, but rather symptomatic relief, pain control, and improvement in quality of life.

Since our understanding of stimulation tolerance is still cursory, recommendations regarding its prevention do not exist. Kumar and colleagues have attempted adjuvant medications and stimulation-free intervals to address the issue—both attempts were met without success, but are still commonly used. SCS has traditionally relied on low frequency tonic stimulation to deliver paresthesia over the target region of pain. A burgeoning frontier of SCS involves the use of high frequency stimulation and burst stimulation—both of which have been reported to provide paresthesia-free pain relief [3, 5, 54]. While initial reports depict efficacy in pain control [7, 54], we pose the question of whether these novel stimulation paradigms are susceptible to stimulation tolerance.

COGNITIVE AND BEHAVIORAL CONSIDERATIONS

Psychological Testing

A significant proportion of patients suffering from chronic pain also live with mental health illnesses. Before a trial of SCS is initiated, we mandate patients to undergo psychological testing [3]. Psychological assessment is regarded as indispensable based on associations drawn from retrospective studies [55, 56, 57]. Furthermore, many insurance companies throughout the United States mandate psychological screening before surgery [57]. Psychological risk factors identified as predictors for poorer outcome in SCS include somatization, anxiety, depression, and poor coping skills. The association of these risk factors with poorer outcomes is not unique to SCS, but is similarly shared with outcomes of other surgical procedures [3]. While some studies have demonstrated an improvement in depression scores following SCS therapy [58], others have failed to show a consistent correlation between level of depression and efficacy of SCS [5, 56].

Psychological Testing: Recommendations

According to the principle of beneficence, clinicians endorse the modality that is expected to provide the greatest good while minimizing the likelihood of harm. To this effect, psychosocial screening for surgical candidates can prevent high risk patients from undergoing invasive procedures from which they are likely to derive little benefit. Additionally, such screening creates the foundation for proper postoperative management and support. Stephens and Ward suggest a three-pronged approach to evaluate patient candidacy for surgical neuromodulation; 1) recognition of psychological risk factors, 2) patient education (regarding surgery, living with implanted hardware, maintenance of therapy), and 3) managing expectations for pain reduction [55].

Recognition of psychological risk factors begins with evaluation by psychologist with experience in chronic pain management. The clinical interview should be supplemented with standardized assessment tools [55]. Although there remains a lack of consensus regarding which screening tools to use, assessments that have gained traction in the neuromodulation community include: the McGill Pain Questionnaire, Beck Depression Inventory, modified Zung Depression Scale for back pain, Minnesota Multiphasic Personality Inventory, Distress and Risk Assessment Method, Patient Health Questionnaire-9, and the Generalized Anxiety Disorder 7-item scale [55, 56, 57]. We find MMPI to be of greatest value.

Psychological assessments should not be the sole basis for exclusion from SCS therapy. Rather, biopsychosocial issues that arise during screening may be factors that are amenable to treatment—thereby improving patient selection. Thus, identification of psychiatric risk factors may help improve post-operative management of mental health or facilitate more suitable, alternative treatment modalities [55, 59]. Psychiatric treatment and surgical management need not be mutually exclusive. Furthermore, literature suggests that improvements in coping skills are associated with reductions in patient-reported pain and disability [60].

CONCLUSION

Spinal cord stimulation continues to grow as one of the most promising modalities of neuromodulation for chronic neuropathic pain. While the morbidity and mortality after SCS are rare, appreciating the vast array of complications—both common and uncommon—will aid clinicians with device implantation, complication recognition, and avoidance of sequelae. Our continued improvement in SCS technology and technique will guide the development of unique applications of neuromodulation.

Chapter 380

EFFICACY OF POST-OPERATIVE ORAL TRAMADOL AND DICLOFENAC SODIUM ON PAIN RELIEF FOLLOWING MANDIBULAR THIRD MOLAR SURGERY: A DOUBLE BLIND, RANDOMIZED CONTROLLED TRIAL

M. Nabeel Nazar* and Ashok K. Ramadorai†

Department of Oral and Maxillofacial Surgery, Saveetha Dental College,
Saveetha University, Chennai, India

ABSTRACT

Surgical removal of impacted third molar results in pain, trismus and swelling. Non-steroidal anti-inflammatory drugs (NSAIDs) routinely used for the control of pain may be associated with severe gastric and bleeding related side effects. The use of centrally acting analgesics may be more useful in this regard. Not many studies have compared Diclofenac sodium with Tramadol. The aim of this study is to compare the efficacy of diclofenac sodium and tramadol in offering pain relief in patients following surgical removal of the third molar. The present study included 98 patients, who presented with impacted mandibular third molar. They were stratified and randomly allocated to one of the 2 groups (Tramadol 50mg and Diclofenac sodium 75mg). Patients recorded their pain intensity after intake of the drugs, in study diaries for a three day period. Patients also noted the global assessments of study medication on a 5-point scale. Comparing the two drugs there was no significant difference in the pain scores or global assessment scores for both the drugs ($P>0.05$). Within the limitations of this study, the pain relief offered by Tramadol was similar to that of Diclofenac sodium. Tramadol may be considered a viable alternative to Non-steroidal anti-inflammatory drugs, for surgical removal of mandibular third molar.

INTRODUCTION

Impaction of the mandibular third molar is a common condition giving rise to symptoms which necessitate its removal. Prophylactic extraction of third molars poses little surgical risk and may be beneficial in preventing disease [1]. Pain, trismus and swelling are the common complications occurring post-operatively. Post-operative pain after third molar surgery is a localized inflammatory pain of varying intensity.

The more prolonged periods of pain and inflammation appear to be integrally involved with the formation and function of the prostaglandins, which are a group of biologically active fatty acids derived from arachidonic acid and linoleic acid. Trauma, heat, anoxia or any stimulus which will result in deformation of the cell membrane or activation of lipolysis will elicit hydrolysis of phospholipids and triglycerides to release arachidonic acid metabolites via cyclooxygenase and lipoxygenase pathways the free fatty acid precursors of prostaglandins. These fatty acids are transformed into prostaglandin endoperoxides, PGD₂, PGE₂, prostacyclin and thromboxanes. Arachidonic acid is also a substrate for lipoxygenase enzymes: Lipoxygenases generate a number of open-chain mono or dihydroxy acids from arachidonic acid via the corresponding unstable hydroperoxy acids, Hydroperoxy Eicosa Tetra Enoic acid (HPETE). 5-HPETE is also the precursor of the recently described leukotrienes. Leukotriene A is identical to a slow-reacting substance released in anaphylaxis and leukotriene B is a very potent chemotactic substance. It is possible therefore, that lipoxygenase products, as well as cyclooxygenase products may contribute to the development of pain and edema in the inflammatory response.

Pain resulting from the surgical removal of impacted third molars is a frequent problem and may affect the patient's post-operative quality of life. Pain reaches maximum intensity within 3–5 hours of surgery. For pain, trismus and swelling control after lower third molar surgery, several non-steroidal anti-inflammatory drugs (NSAIDs) have been used [2-6]. These medications have their therapeutic effect by means of the inhibition of cyclooxygenase (COX), which determines an inhibition of prostaglandin production. Three isoforms of COX are known: COX-1, a constitutive form expressed in almost all tissues, COX-2, predominantly induced and constitutively expressed in a limited number of tissues (renal medulla, prostate, brain and endothelium), and COX-3, a COX-1-derived protein, most abundant in the cerebral cortex and heart. It is believed that COX-2 is the main isoenzyme for pro-inflammatory prostaglandin production, and that the inhibition of COX-3 could represent a primary central mechanism by which NSAIDs like acetaminophen and dipyrrone decrease pain and possibly fever. According to their relative inhibition of COX isoenzymes, NSAIDs can be classified as non-selective, COX-2 preferential or COX-2 selective. Acetaminophen has analgesic and antipyretic effects similar to aspirin. However, it has only weak anti-inflammatory effects and is thought to have a generally poor ability to inhibit the activity of the COX enzyme system in the presence of high concentrations of peroxidases, as are found at sites of inflammation.

The side effects associated with the use of NSAIDs are numerous, but primarily they are related to gastrointestinal (GI), hematologic, and renal disorders, as well as the propensity to cause skin and mucosal reactions. It should be noted that most of the manifestations of these adverse effects occur with chronic dosing of NSAIDs. Therefore, over a long period of time, the continuous inhibition of the COX enzymes becomes increasingly significant. The most profound adverse effect of the prolonged use of traditional NSAIDs is GI disturbance. Because this class of drugs blocks both COX enzymes, the gastric protective functions produced from prostaglandins produced by the COX-1 enzyme are not present. This makes the GI tract susceptible to GI ulcers, dyspepsia, and gastric bleeding. It has been found that gastric and duodenal ulcers are prevalent (15%-30% of patients) at endoscopy in patients taking NSAIDs on a regular basis [7]. Another adverse effect of NSAID use is increased bleeding risk intra-operatively and postoperatively. The inhibition of COX-1 in platelets by conventional NSAIDs results in modulation of platelet function leading to prolonged bleeding [8]. The renal side effects of NSAIDs are also well known and equally concerning.

Diclofenac is a NSAID that is available in an oral immediate-release potassium salt tablet form and a sodium salt delayed-release and extended-release tablet form. Diclofenac has potent inhibitory control of cyclo-oxygenase 1 and 2 sites. In pharmacokinetic studies diclofenac is rapidly and efficiently absorbed from the gastrointestinal (GI) tract.

Tramadol Hydrochloride (1RS, 2RS)-2-[(dimethyl amino)-methyl]-1-(3-methoxyphenyl)-cyclohexanol Hydrochloride, is a centrally-acting synthetic analgesic of the amino-cyclohexanol group with opioid-like effects. It is not derived from natural sources, nor is it chemically related to opiates. It is clinically effective in the treatment of moderate to moderately severe pain with a relative low addiction potential. In acute therapeutic use, Tramadol Hydrochloride produces analgesia against multiple pain conditions, such as post-surgical pain, obstetric pain, terminal cancer pain, and pain of coronary origin, and it has been used as adjuvant therapy in anesthesia. It acts at opioid receptors and also seems to modify transmission of pain impulses by inhibition of mono-amine reuptake. Tramadol Hydrochloride is administered as a racemic mixture of 2 enantiomers that are metabolized by the liver. While the (+) enantiomer has a moderate affinity for the opioid receptors, and inhibits serotonin reuptake, the other enantiomer (-) is a norepinephrine reuptake inhibitor. Although pre-clinical testing has not completely explained the mode of action, at least two complementary mechanisms appear applicable: binding to μ -opioid receptors and inhibition of re-uptake of noradrenaline and serotonin. The opioid-like activity of Tramadol Hydrochloride derives from low affinity binding of the parent compound to μ -opioid receptors and higher affinity binding of the principal active metabolite, O-desmethyl Tramadol, denoted M1, to μ -opioid receptors. The analgesic and anesthetic properties of tramadol in different oral surgical procedures have been studied [9-13].

An extensive review of literature showed us that there were no comparisons of Diclofenac sodium with Tramadol Hydrochloride in offering pain relief following surgical removal of impacted third molars.

METHODS

This is a randomized, double-blind, controlled study. A power calculation showed that a sample size of 80 subjects would detect a 30 % difference in the success rate of the two test groups at a power of 90% (α - type I error of 0.05 and β - type II error of 0.10). Hence a total number of 120 subjects were screened considering a 10% attrition during follow-up to achieve the required sample size. The protocol was approved by the institutional review board, ethical committee and the study was conducted in accordance with the ethical standards for human experimentation established by the Declaration of Helsinki. All patients provided written informed consent before study participation.

Figure 1. Consort flowchart.

Healthy male and female patients aged 18 to 45 years who required removal of impacted mandibular third molar were included in the study. Reasons for exclusion from the study were: known allergy to NSAIDs, hepatic, renal or heart diseases, asthma, diabetes mellitus, hypertension, epileptics, concurrent treatment with immunosuppressants, corticosteroids, history of peptic ulceration, gastrointestinal hemorrhage, pregnancy, use of oral contraceptives, history of NSAIDs use in the past 10 days and evidence of infection at the surgical site.

The study consisted of a pre-study screening visit, a treatment visit (dental surgery, followed by randomization to study drug), and a post-study visit 4 days and 7 days after surgery. Patients who met the inclusion criteria at the screening visit returned after 2 days for surgical extraction of third molars, for which local anesthesia (epinephrine with lidocaine) was administered. One partial or full bony impacted mandibular third molar was extracted under local anesthesia. At the time of surgery, the investigator noted the tooth removed, the duration of surgery, and the impaction score for each tooth (Based on Pederson's difficulty index) [14].

Allocation of patients to treatment was stratified by impaction score (mild or moderate or severe). Patients fulfilling the criteria were randomly allocated from a computer-generated list of random numbers into one of the 2 groups to receive treatment two times a day with Tramadol 50 mg or diclofenac sodium 75 mg (see figure 1). The study drugs were dispensed as identical capsules by an unblinded staff member. Patients were advised to take all the medications orally after meals. The first dose was administered 1 h after surgery. The procedure was described to the patients and written informed consent was obtained. The same surgeon operated on all the patients to avoid any variation in the surgical technique. The operation was carried out under local anesthesia. Anesthesia was by nerve block of the inferior alveolar and buccal nerves with 1.8 ml of 2% lignocaine containing 1:2,00,000 epinephrine. The surgical procedure consisted of a 3–4 cm long buccal incision, elevation of the mucoperiosteal flap, removal of buccal bone using bur, splitting and elevation of the impacted tooth, followed by debridement, achievement of hemostasis and closure of wound by interrupted suture using 3/0 braided silk. Metronidazole 400mg was prescribed to the patients in both groups.

The patients who did not achieve adequate pain relief with study medication were asked to take acetaminophen 500 mg as rescue medication. Patients who had consumed rescue medication were excluded from the final analysis.

Efficacy Assessments

Patients recorded their pain intensity after intake of the drugs, in study diaries at specified time intervals. In addition, they provided a global assessment of study medication at the end of 24 hours post-dose. Each patient was given a copy of the Visual Analog Scale (VAS) with readings from 0 to 10 with a gradation of 1 (from 0 = none to 10 = severe). The patients were asked to use this scale to note their pain intensity after intake of medication and to record it on the pain diary. The global assessments of study medication used a 5-point scale (from 0 = poor to 4 = excellent).

Data Presentation and Analysis

Three parameters were assessed to determine the overall analgesic effect of the drugs : pain relief at the end of 24 hours (TOPAR 24), pain relief at the end of everyday for 4 days (TOPAR 1, 2, 3, 4), patient's global assessment score at 24 hours (GLOBAL24). The data were recorded on a microsoft excel sheet for statistical evaluation using a commercial program (SPSS 19). Age and post medication scores were tabulated and compared using

multiple comparison analysis of variance and post-hoc test. Equality of variances was assessed using Leven statistics, if an equality of variances existed, t-test was employed to identify significant differences between groups. The gender of the patients, type of tooth, the difficulty level of the impaction and the global assessment of functions were compared by chi-square test. The alpha type error (significance level) was set at $P=0.05$ for these analyses.

Table 1. Distribution of patients in Groups I & II based on difficulty scores

Difficulty Score	Group I	Group II	Total
<5	12(30%)	10(25%)	22(27.5%)
5-7	20(50%)	20(50%)	40(50%)
>7	8(20%)	10(25%)	18(22.5%)
Total	48(100%)	50(100%)	98(100%)

RESULTS

All data were analyzed using SPSS 19 software. The total of 98 randomized patients comprised of 58.8% male ($n=58$) and 41.3% females ($n=40$). Chi-square test showed no significant difference between the sexes and ages for both treatment groups. There was no significant difference between the 2 groups in terms of distribution of patients based on the difficulty of impaction (see table 1).

Both the medications brought about a significant pain relief over the four day period ($P<0.05$). There was no significant difference in pain scores between the two groups ($P>0.05$)(see table 2). With regards to global assessment of function, there was no significant difference between the two groups, ($P>0.05$) (see table 3).

Table 2. Pain scores for Groups I & II

Group I (mean $\pm$ SD)	Group II (mean $\pm$ SD)	
Day 1	38.42 $\pm$ 11.059 ^a	37.67 $\pm$ 14.285 ^a
Day 2	22.05 $\pm$ 10.246 ^b	26.58 $\pm$ 12 ^b
Day 3	14.53 $\pm$ 7.686 ^c	16.55 $\pm$ 10.51 ^c
Day 4	3.38 $\pm$ 2.227 ^d	4.05 $\pm$ 5.702 ^d

Within the same group different superscripts indicate statistical significance ($P<0.05$), between groups same superscripts indicate no statistical significance ($P>0.05$).

Table 3. Global Assessment of function for Groups I & II

Global Assessment	Group I No.(%)	Group II No.(%)	Total No.(%)
Very Poor	5(10.4%)	8(16%)	13(13.2%)
Poor	22(45.9%)	22(44%)	44(44.9%)
Fair	12(25%)	9(18%)	21(21.4%)
Good	7(15%)	7(14%)	14(14.2%)
Excellent	2(4.1%)	4(8%)	6(6.1%)

DISCUSSION

Post-operative pain after third molar surgery is a localised inflammatory pain of varying intensity. The initial pain includes the release of various mediators into the local environment, such as arachidonic acid metabolites, 5-HT and bradykinin. These mediators increase the responsiveness of local nociceptors. The afferent activity is relayed to the dorsal horn neurons in the spinal cord, which relay to higher centers where pain is perceived. The two other pathways that may be important to pain control are the descending inhibitory pathway and the sympathetic nervous system, which is implicated in the maintenance of pain states [15]. The problem of dental pain can be tackled using peripherally acting drugs or a centrally acting analgesic.

The most prevalent methods to prevent peripheral sensitization include administration of: NSAIDs [2-6], which prevent peripheral sensitization by reducing prostaglandin synthesis at the site of surgery; regional anaesthetics [16], which block afferent nociceptive impulses prior to incision; opioids [17], which modulate afferent input by blocking the postsynaptic receptors and decreasing neurotransmitter release or by activating inhibitory pathways; and NMDA-receptor antagonists [18], which inhibit activation of N-methyl-D-aspartate (NMDA) receptors in the human spinal cord, thus preventing the main mechanism of central sensitization.

Results of clinical trials reported in the literature about pain after removal of third molars compare the analgesic effect of NSAID with placebos [19], or other NSAIDs [3, 6, 20-22] or test regimens only before or after the surgery [5]. There are also reports of NSAIDs compared with tramadol [4], however they used the intra-venous route for the administration of the drugs. Although placebo controlled clinical trials are considered the norm and gold standard for evaluation, this study did not utilize a placebo for comparison because of ethical reasons. Some studies which have utilized a placebo for comparison also placed the patients on rescue medication, however patients consuming the rescue medications were excluded from the study. This will induce a confounding factor. In the present study patients were advised to take a rescue medication of acetaminophen 500mg, if they had persisting pain after intake of the test drugs. Two patients in both the groups had taken rescue medications and therefore were excluded from the study. This study utilized a stratified random sampling method based on the severity of impaction as determined by Pederson's difficulty score. This was done to ensure that patients were equally distributed between the two study groups based on the difficulty level. However an attempt was not made to correlate the difficulty level with the pain relief. This needs further investigations.

The results of this study showed that the pain scores, and hence indirectly the pain relief, were not significantly different when either Diclofenac sodium 75mg or Tramadol Hydrochloride 50mg were prescribed as post-operative medications. Comparing the pain scores between the two treatment groups at the end of 24 hours, although Tramadol Hydrochloride brought about a marginal increase in the pain relief, this difference was not statistically significant when compared with Diclofenac sodium. Both the medications brought about a significant pain relief over the four day period. Furthermore both the drugs did not bring about any adverse effects and there was no significant difference in the global assessment score of both the drugs. Similar results have been reported comparing these two study drugs in pain control following bimaxillary osteotomy as well as osteoarthritis [23, 24].

However such a comparison has not been made for pain management following surgical removal of impacted third molars. Studies have reported that intra-muscular (IM) administration of tramadol pre-emptively offered better pain relief than post-operative administration via the same route [9]. It is also been shown that intra-venous (IV) tramadol provides better pain relief than oral tramadol, but administration of tramadol via the IM or IV routes could result in side effects like depression and sedation [10].

The possible mechanism by which tramadol brings about pain relief as effective as NSAIDs is an interesting factor which warrants discussion. Opening of potassium channels located in the primary afferent nerve endings produces anti-nociception and represents an important step in the peripheral anti-nociceptive effect of several NSAIDs. Activation of the NO-cyclic guanosine monophosphate (GMP) pathway could also induce anti-nociception through the opening of potassium channels. Such a mechanism has been implicated for the anti-nociceptive action of rofecoxib and lornoxicam [25, 26] both of which are NSAIDs. It is possible that both Tramadol Hydrochloride (in addition to its centrally acting mechanism) and Diclofenac sodium could share the above mentioned mechanism. Another probable reason is the involvement of transient receptor potential vanilloid channels (TRPV-1), which have been implicated in pain signaling. TRPV-1 plays a major role in hyperalgesia and allodynia, and is expressed in both the parasympathetic nervous system and central nervous system [27]. TRPV-1 is sensitized by prostaglandins and other inflammatory mediators leading to a potentiation of currents through the channel. Activation of TRPV-4 channel does not occur by the action of a single inflammatory mediator but rather through the concerted action of multiple mediators [28]. It could be hypothesized that Tramadol Hydrochloride brings about inhibition of TRPV channels more effectively than Diclofenac. However further research is required in this direction.

Apart from analgesia, Tramadol Hydrochloride may produce other symptoms similar to that of opioids including: dizziness, somnolence, nausea, constipation, sweating and pruritus. However, Tramadol Hydrochloride causes significantly less respiratory depression than morphine. In contrast to morphine, Tramadol Hydrochloride has not been shown to cause histamine release. At therapeutic doses, Tramadol Hydrochloride has no clinically significant effect on heart rate, left ventricular function or cardiac index. Orthostatic changes in blood pressure have been observed. Several studies indicated that unlike other opioids, Tramadol Hydrochloride was not associated with clinically relevant side effects. Drowsiness, nausea, and dizziness are the most common adverse effects[29]. In a study of the effects of Tramadol Hydrochloride on dentoalveolar surgical pain by Collins et al., 39% of patients on high doses of Tramadol Hydrochloride (100 mg four times a day orally), 12% on moderate doses (50 mg 4 times a day), and 6% on low dose (50 mg 2 times a day) withdrew from the study owing to nausea, vomiting, dizziness, or drowsiness [30] and in another study [9], seven of 40 patients reported drowsiness and three reported nausea. In our study, Global assessment of function was used to assess the side effects and 10% of 48 patients showed very poor compliance, of which 3 patients had nausea and 1 had vomiting, however none of the patients discontinued the medication.

The clinical application of the results of this study should be exercised with caution. This study evaluated only one type of NSAID i.e., Diclofenac sodium and hence, generalization or applicability of the results to the entire category of NSAIDs may not be possible. This warrants further inspection. Therefore Tramadol Hydrochloride may be considered as a viable alternative to Diclofenac sodium in patients where NSAIDs are contraindicated.

CONCLUSION

This study suggests that Tramadol Hydrochloride is a safe and effective alternate to NSAIDs, for mandibular third molar surgery.

Chapter 381

MANAGEMENT OF FAILED BACK SURGERY SYNDROME AND RELATED DISORDERS

Angelo Rafael Cunha de Azevedo*, MD
and William Omar Contreras Lopez, PhD, MD
University of São Paulo, São Paulo, Brazil

ABSTRACT

Fail Back Surgery Syndrome (FBSS) and post laminectomy syndrome are commonly associated with spinal adhesive arachnoiditis and Complex Regional Pain Syndrome (CRPS). Post laminectomy and FBSS have common symptoms and their treatment by spinal cord surgery is typically unsuccessful, with subsequent development of lumbar and radicular pain, despite the use of modern physiatrics techniques and pharmacological approaches. Spinal arachnoiditis is an inflammatory process involving all three meningeal layers or the nerve roots and commonly produces persistent pain. Patients with inappropriately long post-surgery immobility periods are at risk of CRPS, which is characterized by functional limitations in walking, neuropathic pain, edema and colors changes in the affected limb. Among drugs for the treatment of neuropathic chronic pain established are Gabapentin, Tramadol, Venlafaxine or Duloxetine being most commonly applied as a multi-therapy approach. Physical therapy often helps with pain relief and gain of movement. Here we performed spinal cord stimulation (SCS) to treat FBSS. When well indicated, SCS can achieve up to 50% pain relief in VAS (visual analogic scale). Alternative treatment options include continuous intrathecal morphine delivery and ozone therapy by spinal epidural endoscopy, which have been reported to reduce pain by more than 40%.

Keywords: lumbar pain, fail back surgery syndrome, complex regional pain syndrome, spinal cord stimulation

INTRODUCTION

The term Fail Back Surgery Syndrome (FBSS) describes cases in which therapy has failed because of structural abnormalities in the back and/or psychosocial influences. FBSS is typically assessed by resonance imaging techniques, together with physical examination and an evaluation of the patient's medical history. Concomitant evaluation of psychosocial issues is mandatory and should include a reasonable attempt at physical rehabilitation, giving attention to both local factors and general functioning. If intensive conservative rehabilitation efforts fail, those patients principally suffering from physical abnormalities can be treated by reparative surgery or pain-relieving procedures. Although reparative surgery can successfully address initial surgical failures, some patients fail to benefit and have their conditions worsened by such procedures. Most patients suffering from FBSS are incapacitated by psychiatric, psychologic and social/vocational factors, which are only indirectly related their back complaint. Decisions concerning the most appropriate treatment are often made by patients, attorneys, disability determination systems, employers and judges, which can be influenced by extraneous motives, including financial gain and personal bias, and often reflect the current dearth of available information about FBSS [1].

Back surgery can fail if patients are erroneously selected for intervention, in cases of lumbar disc protrusion and if lateral recess stenosis goes undiagnosed. Patient motivation levels also affect surgical outcome. The ideal candidate FBSS patient for surgical intervention would have sciatica that is more severe than backache, a recurrent or residual disc protrusion associated with the stenosis and high levels of motivation that are not affected by workers' compensation (WC) or other insurance claims or benefits [2]. Vik et al. compared the patient outcomes of 211 patients with unilateral sciatica operated on for lumbar disc herniation that were either reoperated or operated on only once. Eight years after operation, the reoperated patients had a significantly worse outcome than the operated once patients. In addition, reoperated patients with preoperatively confirmed recurrence of the same disc had a better outcome than reoperated patients without preoperative signs of a recurrence [3].

FBSS is a relatively frequent (5–10% of patients) complication of lumbosacral spine surgery [4]. In a study evaluating trends associated with surgery for lumbar spinal stenosis in older adults, the authors identified a 15-fold increase in the rates of complex fusion procedures from 2002 to 2007, with higher rates of life-threatening complications (5.6%) compared to simple decompression (2.3%). A higher rate for rehospitalization within 30 days was also noted with complex fusion (13%) compared to decompression (7.8) [5]. In ~11% of FBSS patients, low sacral arachnoiditis adhesive is the primarily responsible for incapacitation. Data from the 1990 indicate that about 25% of the patients that underwent back surgery in the United States were either not improved or made worse [6].

Currently, the number of FBSS patients is growing. This is partly due to a growing number of young patients undergoing lumbar fusion, which is surprisingly rarely discussed among physicians. The term *fusion*, which implies rigid fixation, has been replaced with *arthrodesis* (from the Greek: arthro—joint, desis—to bind) and applied to many pathologies of lumbar instability or misdiagnosed chronic lumbar pain. We propose that, among spine surgeons, there is a widespread need for the recognition that motion-preserving stabilizations often represent a better surgical option than multilevel pedicle screw and rod rigid approaches for patients with multilevel degenerative disease [7].

PATHOLOGY

Spinal arachnoiditis is an insidious disease caused by an inflammatory process of the arachnoid membrane and can arise from myelograms with oil-based radiographic contrast agents and multiple back surgeries [8]. Spinal arachnoiditis involves all three meningeal layers or the nerve roots and causes persistent pain in 6–16% of postsurgical cases [9]. During the initial phase of this process, the roots in the intrathecal trajectory present swelling, with the hyperemia and an important fibrinous exudate, completely filling the subarachnoid space. In the absence of the cell fibrinolytic liberating enzyme, fibrin is deposited, covering the nerve roots and arachnoid, ultimately resulting in adhesions between cellular components. Nevertheless, fibroblast proliferation continues throughout this phase. The second phase is characterized by collagen deposition leading to adhesion between the nerve roots and the meninges. In the second phases, autoimmune factors determine the order of the procedure, as well as its progression. In some instances, the inflammatory reaction is so pronounced that the scar tissue completely occupies the sub-arachnoid space, progressing from a focal to totally blockage. Calcification of the fibrous bands may also occur [10]. The patient usually describes a continuous burning sensation at the sacral area, severe pain down the back of one or both legs, without sciatic distribution, tingling pain when walking, burning at the knees, while tingling and pain in the feet, calves and ankles is usually ameliorated. The pain is normally reduced when the patient lies flat [11]. Lumbar adhesive arachnoiditis can be subdivided into three injury types: (1) the roots clustering in the center of the thecal sac; (2) the roots are adhering to the periphery of the thecal sac - aspect of "empty bag"; and (3) conglomerates root and scar tissue that fills the subarachnoid space - pseudo-tumoral aspect.

Complex regional pain syndrome (CRPS) is used by the International Association for the Study of Pain (IASP) to describe disorders characterized by spontaneous or stimulus-induced pain that is disproportionate to the inciting event and accompanied by a wide variety of autonomic and motor disturbances in highly variable combinations. The term CRPS has been subdivided into type I and type II. CRPS I is intended to encompass reflex sympathetic dystrophy and similar disorders, without a nerve injury, while CRPS II occurs after damage to a peripheral nerve [12].

	CRPS I	CRPS II
Etiology	No lesion	Nerve lesion
Localization	Distal extremity Independent to nerve's distribution	Any peripheral site Confined to nerve's distribution
Spreading of Symptoms	Obligatory	Rare
Spontaneous Pain	Eventual Mostly deep Orthostatic component	Several Superficial No orthostatic component
Mechanical Allodynea	Most Patients With Spreading Tendency	Obligatory in Nerve Distribution
Autonomic Symptoms	Distally Generalized With Spreading Tendency	Related To Nerve Lesion
Motor Symptoms	Distally Generalized	Related To Nerve Lesion
Sensory Symptoms	Distally Generalized With Spreading Tendency	Related To Nerve Lesion

CRPS-I is more commonly associated with FBSS than CRPS-II. Although it has long been hypothesized that CRPS is mediated by the sympathetic nervous system, its pathophysiology is not yet fully understood. The most popular theory is that there is a mismatch between the sensory input and motor output, leading to a disorganization of motor programming in cortical structures. Motor control studies have suggested that this mismatch could be corrected using a proprioceptive feedback mechanism [13, 14].

Traditionally, CRPS was considered a progressive condition, described in three stages: (1) the “acute stage,” characterized by a painful, swollen, warm, red limb; (2) the “dystrophic stage,” the limb was said to cool and appear cyanotic, with changes to hair and nail growth, osteoporosis, stiffness, and muscle wasting; (3) the “atrophic stage,” irreversible atrophy of bones, muscles and nails [15].

EVALUATION

Iophendylate (Pantopaque), a liposoluble dye used during myelography, was identified as a cause of arachnoiditis adhesiva and its use banned in Scandinavia and rest of Europe in (1948) and only much later (in 1980) in the US.

Dyes are useful during myelography, helping with diagnosis and treatment. The lesions associated with arachnoiditis are usually discovered at myelography and/or operation. When the myelographic defects do not conform to the classical lumbar disc condition, then arachnoiditis is probably the presenting pathological condition. Among etiologic agents, water-based contrast agents are less commonly applied. The closer the contrast material is to isomolarity, the less likely adhesions are to develop. The current dye in use, Iohexol-300 Parenteral (phenterminehydrochloride), is a water-soluble isomolaric compound that is reabsorbed by the cerebrospinal fluid, requiring no special removal steps [16].

The CT myelography better defines intradural injuries of arachnoiditis. It allows opacification of certain areas of the sub-arachnoid space, which are invisible during myelography, allowing better diagnosis. In most cases, arachnoiditis is demonstrated by plain-film and CT myelography, although abnormally configured nerve roots can also be detected by magnetic resonance imaging (MRI). For the diagnosis of moderate to severe arachnoiditis, MRI data typically correlate with the findings of CT myelographic and plain-film myelography [17].

MRI can be used to distinguish between arachnoiditis subtypes. T2-weighted sequences offer the same signal as axial view CT myelography, with the roots as hyposignals within the hyperintense CSF. This sequence is useful for defining the distribution of the intrathecal roots. However, the pathology may be masked by a hyperintense signal during fibrosis, which can simulate the hyperintense CSF. The T1-weighted sequences are the most sensitive, both in sagittal and axial sections, with the roots having an intermediate signal within the hypointense CSF.

Evaluation by MRI is critical because it provides evidence for continued pain and functional incapacitation in 19% of cases. The causes of delayed recurrence of lower back and sciatic pain are multiple and include arachnoiditis, epidural fibrosis, facet osteoarthritic degenerative change, instability, new intervertebral disc herniation, spinal stenosis (lateral or central, from postoperative bony overgrowth) and vertebral osteomyelitis [18]. FBSS can

arise from both successful and unsuccessful osseous fusions. Successful lumbar spinal surgery with osseous fusion results in altered biomechanics, with hypermobility of the adjacent levels, causing accelerated degenerative changes. Unsuccessful osseous fusion can result in pseudoarthrosis. Findings of T1 hypointensity and T2 hyperintensity persisting between the vertebral body and bone graft for more than 6 months are suggestive of pseudoarthrosis [19].

Thermography has an 80% sensitivity and 60% specificity for CRPS patients that have undergone the procedure [20]. The cold stress test can also be used in CRPS evaluations. The patient is acclimated for 15 min unclothed in an isolated room maintained at a mean temperature of $23 \pm 2^\circ\text{C}$ and a relative humidity of 50%. A temperature asymmetry between the affected and unaffected extremities greater than 1.00°C is considered a positive finding [21].

Figure 1. Thermography data. The initial measurements in lower limbs were 19.5°C and 22.9°C . After 10 min, these values have changed to 20.7°C and 23.2°C respectively, indicating that the Sp1 (right leg) is positive for CRPS-I. Image courtesy of Dr. Gilberto de Paula.

TREATMENT

CRPS treatment options usually include a range of physical, psychological, medical and surgical therapies. In our center, we subscribe opioids, anticonvulsants and antidepressants to control secondary back pain. Table summarizes the drugs typically used to treat CRPS.

Amongst the invasive pain treatments available for FBSS, we usually offer: (1) spinal cord stimulation (SCS); (2) epiduroscopy and (3) continuous morphine intrathecal pump.

SCS is less expensive and more effective than reoperation in selected FBSS patients. North et al., found that patients who crossed over to another therapy had less successful outcomes than patients who did not cross over; 2 of 8 patients who did not crossover from reoperation were successes, whereas none of the 5 who crossed over to reoperation and 7 of 14 who did not crossover from SCS were successes, versus 5 of 13 who crossed over to SCS [22].

In our experience, SCS is advantageous for the treatment of FBSS, which is in line with the findings of international studies. Boswell et al. (2005 and 2007) have recommended SCS to treat CRPS and FBSS [23, 24]. In 2007, the European Federation of Neurological Societies (EFNS) launched a task force to evaluate the evidence for the use of these techniques and to produce relevant recommendations [25]. Using literature data from 1968 to 2006, SCS was

shown to be efficacious in FBSS and Type I CRPS (level B recommendation) [26]. A Dutch Multidisciplinary Guideline for Invasive Treatment of Pain Syndromes of the Lumbosacral Spine Task force has proposed that SCS is recommended for patients with FBSS who have pronounced leg pain and for whom conservative therapy has failed [27].

	Class	Dose/day	Action	Common Side-effect
Venlafaxine	antidepressant	75-150mg	Dual (Noradrenaline and Sertraline)	Vomit
Duloxetine	antidepressant	60-120mg	Dual (Noradrenaline and Sertraline)	Not reported
Pregabalin	anticonvulsant	150-600mg	Ca ⁺ channel blocker	Drowsiness
Gabapentin	anticonvulsant	600-2400mg	Ca ⁺ channel blocker	Not reported
Oxycodone	Opioid	30 – 120mg	Sintetic agonist	Itch
Codeine	Opioid	120mg - up	agonist	Itch
Tramadol	Opioid	200-400mg	Sintetic agonist	Itch
Morphine	Opioid	40mg - up	agonist	Itch, constipation

There are two types of electrode that can be used during SCS implantation: a single tubular lead (4–8 contacts) or paddle lead (2 or more columns and 8–20 contacts). The surgery techniques depend on the type of electrode to be implanted. To treat pain in lower limbs and lumbar pain, electrodes are usually implanted on the epidural space of the D9 intervertebral disc spaces.

The patient is positioned in the prone position with a pillow under their hips and sedated with dexmedetomidine hydrochloride. The procedure is performed under aseptic conditions with antibiotic (prophylaxis) and requires the use of fluoroscopy. With the tubular lead, the puncture is made with a Tuohy needle held laterally to L3-L4 levels on a peduncular line, with the needle positioned toward the midline using C-arch fluoroscopy. After withdraw of the guide thread, the electrode is carefully introduced through the needle and the tip of the lead is slipped up to T8-9 intervertebral disc spaces.

Figure 2. An ANS Penta™ paddle lead 5-column with 20 contacts (A) and tubular lead with 8 contacts (B). Drawing courtesy by St. Jude, Brazil.

Figure 3. (A) Preview by arc-C fluoroscopy of 3-column lead positioned. (B) Small incision and flavectomy, showing the electrode on the epidural space. (C) After the extensions transposed, the lead is connected to a pulse generator.

When using the paddle lead, the procedure is performed with the patient in the prone position, following a protocol similar to the puncture method but on fully endovenous anesthesia. The T9–T10 spinal process level, which will be open, is marked on the skin after visualizing by C-arch fluoroscopy. A sharp dissection is performed to the point of the spinal posterior ligaments and flavectomy is performed. The epidural space is then examined and tested by probe before passing the paddle electrode, which will be positioned on the T8–9 intervertebral disc spaces and stimulate to test the sensitivity level. Also, the stimulation can be performed through an external disposable extension during 7 days for a test. The pulse generator is implanted and the external disposable extension removed, after these 7 days during a second surgery.

Patients that have undergone a stimulation test appear to have a better predictive value (in almost 90% of cases) than those that did not undergo a stimulation trial. Furthermore, the success of SCS depends on the selection of patients based on extensive interdisciplinary examinations following a combination of physical, psychological and medical therapies. Pain relief is rated as good reduced by more than 50%. The important advantages and disadvantages of the electrode types are shown in the table below.

The programming parameters generally begin at an amplitude of 3–10 mA, frequency 50 Hz and pulse width of 90–250 μ sec. Most patients recover function and improve at low

stimulation, however, high-frequency SCS (1–10 kHz) is sometimes required difficult-to-treat patients with chronic back pain [28].

	Tubular lead	Paddle lead
Implantation	Easy to do by puncture	Need open the skin and muscles
Migration/displacement	Common	Rare
Programing	Until 8 contacts	More than 8 contacts option
Fracture	Common	Rare
Side-effects	Multidirections, may stimulate posterior areas to electrode	One steering, stimulate anterior area to electrode

Epidural fibrosis or arachnoiditis may account for as much as 20–36% of all cases of FBSS. Based on the U.S. Preventive Services Task Force (USPSTF) criteria, the required evidence level for endoscopic adhesiolysis is Level II-1 or II-2 for short- and long-term relief respectively [29]. Although serious complications can arise from the pressure increase in the epidural space during epiduroscopy, patients have an average reduction of lumbar pain of 44% and a 61% reduction in leg pain, with 44% improvement within the first 6 months [30].

In our service, endoscopic adhesiolysis is carried out under local anesthesia with the patient awake, thus avoiding potential unrecognized pressure effects in the epidural canal. Light sedation and analgesia are sometimes required to ensure total patient cooperation while maintaining verbal contact. The patient is positioned in a prone position with a pillow under their hips. The procedure is performed under aseptic conditions with antibiotic (prophylaxis) and requires the use of fluoroscopy. A puncture is then made using a 17G Tuohy needle through the sacrococcygeal ligament, followed by a caudal epidurogram to confirm needle placement. The Seldinger technique is then performed by a dilator placement and inserted sheaths through a small incision. Next, a fiber-optic microendoscope (Flexible Fiber Optic Endoscope - Model 3000E; Myelotec®, Roswell, GA, USA) is introduced into the epidural space through the appropriate introducer to obtain video images. Slow irrigation with saline allows visualization of the epidural space by gentle distension. Blunt dissection coupled with hydrostatic distension of the epidural space create a pocket, through which the injected drug can access the symptomatic nerve roots. After adhesiolysis, the patient receives 20 mL of oxygen–ozone mixture at a concentration of 30 µg/mL, obtained from an ozone generator (Medplus Philozon®, Balneário Camboriu, SC, Brazil). After the procedure, the patient is left at rest for 2–4 h in the supine position before being released from the hospital [30].

Intrathecal opioid therapy in general indicated for pain sensitive to opioid medication. However, due to increasing systemic side-effects such as nausea, vomiting, constipation or central nervous system depression, oral or intravenous opioid therapy alone is no longer acceptable.

The targets of intrathecal drug application are the pre- and post-synaptic receptors in the dorsal horn of the spinal cord [31]. After direct intrathecal application, very high concentrations of morphine can reach the receptor sites. Approximately 79% of morphine glucuronation is assumed to take place in the liver [32]. Recently, glucuronide formation was also detected in human brain tissue samples [33]. Because of the proximity of the opioid receptors, even minute amounts of metabolites may have significant pharmacological effects.

Figure 4. Flexible fiber optic endoscope and irrigation with saline solution (left). Intradural view after puncture of the dural sac at the D12 level (right).

In a study conducted in our hospital, the mean intensity of pain was reduced from 9.5 to 4.6 according to VAS (a 48.5% reduction). The mean daily dose of morphine necessary for pain control became constant after the sixth month of treatment and there was improvement in the quality of life. Side effects inherent to drug treatment may occur, although these are more frequent at the beginning of the treatment and become more tolerable after the first month of treatment [34].

There are currently two treatment modalities for pumps: (1) constant infusion and; (2) bolus infusion. There are also two pump types: programmable and non-programmable. In general, pumps have a maximum capacity and infusion time according to the dose to be used. Prior to the use of intrathecal morphine, patients are typically receiving high doses of oral opioids and have already experienced side effects. Before pump implantation, patients undergo an epidural morphine bolus trial by external catheter and receive up to 10 mg/day. Those showing good results (improvement of at least 50% on VAS) proceed to pump implant.

Infection, distal catheter obstruction, catheter migration, catheter disconnection, leakage and persistent side effects (vomit, drowsiness, itch, tachycardia) are complications associated with pump implant. In a study of 122 patients, approximately 30% of complications associated with implants were mostly pharmacological and transient [35]. In the case of infections, we recommend full implant removal because of the risk of meningitis and granulomas.

Technically, the procedure is performed by puncture and the catheter guided to the desired level by fluoroscopy. We usually perform the puncture with a Tuohy needle on the back midline (L3–L4) intradiscal space and pass the catheter through the needle, sliding gently toward the T6 vertebral level. Then, after insertion and fixation, the catheter is transposed by a cannula from the back of the abdomen and connected to a pump.

CONCLUSION

Fail Back Surgery Syndrome is an ensemble of pathologies involving unwieldy pain induced by drugs and physiotherapy, often leading to disability. The causative factors of FBSS should be identified in order to direct treatment. In our department, we discourage reoperations for fusions. Here, we describe three FBSS treatment options (Spinal cord stimulation, epiduroscopy and continuous intrathecal morphine pump) and report patient outcome results comparable to those typically found in the literature.

ACKNOWLEDGMENT

For PhD., MD Erich Talamoni Fonoff, whom I acquired knowledge and taught me functional treatment for pain.

Chapter 382

HEMODYNAMIC COMPLICATIONS ASSOCIATED WITH PRONE POSITIONING IN LUMBAR SPINAL SURGERY

Alessandra D'Ambrosi*, MD and Francesco Fedele†, PhD

Department of Cardiovascular Science “Sapienza” University of Rome, Rome, Italy

ABSTRACT

Prone positioning is required in operations such as spinal surgery. Changes in cardiac function in the prone position have been studied with various methodologies. Several studies have investigated changes in term of cardiovascular complications and hemodynamic abnormalities. The aim of this chapter is analyzed the pathophysiology, comorbidities and preventive methods of cardiovascular complication during spinal surgery. A literature review utilizing PubMed was performed identifying relevant articles that addressed cardiovascular complications associated with prone surgical positioning in spine surgery.

Keywords: spinal surgery, prone position, cardiovascular

INTRODUCTION

The neurosurgical procedures are often very long lead times. Some postoperative complications may be related to incorrect positioning. Patient positioning on the operating table is an important moment of perioperative nursing care. The importance of this procedure should never be underestimated because several factors as immobility, time of surgery and synergistic effect of mechanical pressure and anesthesia, may be cause of complications [1].

In particular, the prone surgical positioning is adopted in spine surgery and in some operations performed in the posterior fossa. The transition from supine to prone position is a very delicate phase and is associated with several important cardiovascular complications

* Corresponding Author's Email: alessandra.dambrosi@gmail.com.

† Corresponding Author's Email: francesco.fedele@uniroma1.it.

(e.g., Bradycardia and hypotension). In this positioning, the ECG monitoring and invasive pressure and check that there are no alterations or kinking of the endotracheal tube is very important.

METHODS

Pathophysiology

In prone position it is possible to find a reduced cardiac filling pressures with reductions in stroke volume in relation to any excessive lowering of the legs or femoral vein or the vena cava compression. The decrease in cardiac output seen on turning prone is considered to be a result of reduced stroke volume. The resulting decrease in arterial pressure is countered by a compensatory sympathetic tachycardia and an increase in peripheral resistance [2].

A decrease in pre-load is thought to be responsible for the reduced stroke volume that is seen. Many factors contribute to a decrease in pre-load and include [7]:

- caval compression;
- blood sequestration;
- increased intra-thoracic pressure with poor positioning and chest wall compression;
- positive pressure ventilation and PEEP.

Because of baseline postural hypotension and decreased cardiac function in the prone position, hypovolemia in the prone patient can exacerbate hypoperfusion to multiple organ systems and may increase the likelihood of acute kidney injury, especially during procedures with high blood loss [2, 3].

The abdomen should be free from crushing, so as not to congest the vertebral venous plexus through the anastomotic circle that connects them to the inferior vena cava, with increased intraoperative bleeding. The mechanical ventilation may be compromised by incorrect positioning in pronation, in fact, if the abdomen is compressed viscera push the diaphragm, resulting in an increase of the ventilation pressures (peak and plateau) resulting in increased risk of barotrauma and reduced venous return to increase central venous pressure. The positioning of cushioned under the shoulders and on the iliac crests, allow to obviate to these occurrences [2].

Comorbidities

The history for heart failure or ischemic coronary disease represents the relative complication at prone positioning. Shimizu M et al. evaluated cardiac function in the supine and prone positions in 90 patients without atrial fibrillation who underwent (99m) Tc-tetrofosmin quantitative gated single-photon emission computed tomography. Three groups of 30 patients each were classified as “no history of myocardial ischemia or cardiomyopathy” (Group A), “history of myocardial infarction” (Group B), and “ischemic heart disease without myocardial infarction history” (Group C). Ejection fraction changes occurred only in Group B, and diastolic function changes occurred in Groups B and C, but not in Group A. The changes caused by prone positioning were more severe in the patients with low cardiac function [3].

The aorta injuries are rare during posterior spinal surgery, but can result in catastrophic complications. Qiu XS et al. analyzed that there are not prior studies that have used MRI images obtained with patients in the prone position for the purpose of systematically evaluating the potential risks of aorta injury due to thoracic pedicle screw misplacement (TPS). Qiu XS et al. evaluated the potential risks of aorta injury from thoracic pedicle screw (TPS) misplacement in right thoracic adolescent idiopathic scoliosis (RT-AIS) patients who are in the prone position. In conclusions prone positioning may increase the risk of aorta injury in RT-AIS patients, particularly at T5-T6 and T11 even if a left TPS just barely touches the anteriolateral or lateral cortex of the vertebrae [5].

The susceptibility to thromboembolism represents one of comorbidity in the prone positioning, however, can be easily prevented with the use of anticoagulants. Where there is a contraindication to the use of anticoagulants, you can place an Inferior Vena Cava (IVC) filter. Chalhoub V. et al. reported a case of a case of an IVC filter migration to the right ventricle occurring while a trauma patient was undergoing spinal surgery in the prone position. The prone position during surgery can induce anatomic and hemodynamic changes in the IVC. This may contribute to the migration of IVC filters. Careful handling and positioning of patients with IVC filters is recommended to avoid a sudden increase in IVC pressure that may predispose to IVC filter migration [8].

Prone positioning for spine surgery has also been associated with rare airway and vascular complications. Airway obstruction has also been reported in a patient with Duchenne muscular dystrophy and lordoscoliosis with concomitant airway malacia who underwent spine surgery in the prone position. Vascular complications including femoral artery ischemia and avascular necrosis of the femoral head are other rarely-described complications of prone positioning. Pressure on the arteries and inguinal area combined with reduced venous outflow and hypotension from anesthesia has been implicated in cases of avascular necrosis of the femoral head [9].

Preventing Cardiovascular Complications

A study using transoesophageal ECHO compared changes in hemodynamic and cardiac function after prone positioning using different prone positioners. Dharmavaram et al. measured cardiac index, stroke volume, and cardiac output in patients placed on the differing

supports. The effect on all cardiovascular parameters was seen with the Jackson table, whereas the cardiac index was decreased when prone on the Wilson table and the Andrews support (knee-chest position) [6, 7].

The jack-knife prone position has been shown to cause a decrease in cardiac index, a bradycardia, and raised mean arterial pressure that returned to supine values when the patients were placed in the Trendelenburg position.

Variabilities in pulse pressure and stroke volume are greater in the prone position, compared with the supine position, and both can be used to predict whether the anaesthetized ventilated prone patient will respond to a fluid challenge. Adequate fluid replacement reduced hypotension and hemodynamic instability after prone positioning. The Jackson spine table and longitudinal bolsters had minimal effects on cardiac function, and should be considered in patients with cardiac dysfunction.

CONCLUSION

Prone positioning complications associated with spine surgery can cause patient morbidity. These complications, careful patient positioning, efficient use of anesthesia time and avoidance of intraoperative hypotension may help reduce the incidence of prone positioning related complications.

Chapter 383

OPEN SURGERY IN THE OSTEOPOROTIC SPINE

Demo Eugenio Dugoni, MD

Department of Neurology and Psychiatry, Neurosurgery,
“Sapienza” University of Rome, Italy

ABSTRACT

Open surgery in the osteoporotic spine is a great challenge. The poor quality of the bone, the age of the patients and comorbidity make surgical strategy very difficult. Open surgery is the only possible treatment in case of neurological symptoms due to spinal stenosis secondary to vertebral compression fracture and subsequent deformity. When the treatment is open surgery, the main difficult is the failure of the implant. Over the years, very different technique has been developed in order to reduce the risk of this complication. To date the best strategy seems to be multiple points fixation with vertebral body augmentation. It is very important to choose the length of the instrumentation respecting the biomechanic of the spine avoiding excessive corrections. Vertebroplasty and kyphopalsty are the important tools to increase the strenght of the bone. Different kinds of pedicle screws are today available in order to increase the risk of pullout.

Keywords: osteoporosis, compression fractures, open surgery, vertebral body augmentation

INTRODUCTION

Osteoporosis is a pathological condition predisposing to the occurrence of fractures through the decreased bone strength. In the United States, 10 million people suffer from osteoporosis, and an additional 34% of people (including more than 55% of the population over age 50) is at risk of developing osteoporosis. 700,000 vertebral compression fractures occur among this group of people affected by osteoporosis. A vertebral compression fracture occurs in about 25% of American women who reach menopause. Although osteoporosis considered a disease of the female gender, 33% of men over the age of 75 are affected by this pathology. It represents, in the elderly population, a significant cause of mortality and morbidity. In spinal pathology osteoporosis is an important condition predisposing to the

development of progressive deformities potentially cause of neurological disability. A compression fracture, in an osteoporotic patient, may produce several changes in local and global structure of the spine such as kyphosis, secondary stenosis to deformity and sagittal imbalance. The main symptom in the early stage of an osteoporotic vertebral collapse is pain. About one third of patients with a vertebral osteoporotic fracture continues to complain of pain despite medical therapy. Similarly, the several different medical treatments with calcium, vitamin D, bisphosphonates, raloxifene, hormone therapy, although very effective, not completely protect patients from the risk of an osteoporotic vertebral fracture, which occurs in about 15% of clients in treatment. In addition, there are the patients non-responders and non-compliants. The number of elderly patients with severe osteoporosis observed by the spinal surgeon is increasing. Surgical treatment of these patients has some peculiar difficulties. In the presence of neurological deficits, the only possible treatment is spinal decompression and stabilization but the procedure, in particular if performed with pedicle screws, has a very high risk of failure because of the loss of bone strength.

PHYSIOPATHOLOGY

Osteoporosis is a disease characterized by a decrease in bone mass which leads to a reduction of the structural support capacity of the spine. Primary osteoporosis is classified into two types: type 1 affects women in post-menopausal age and type 2 affects individuals over 70 years old and configure as a bone loss associated with aging. Secondary osteoporosis is defined as the reduction in bone mass due to pathological or iatrogenic conditions such as endocrine disorders, chronic inflammatory conditions or prolonged corticosteroid therapy. Primary osteoporosis can be further framed as osteoporosis with high turnover in which the excessive osteoclast activity is not balanced by the osteoblasts activity, resulting in bone loss (osteoporosis type 1 primary, post-menopausal); osteoporosis with low turnover in which osteoblastic activity decreases progressively (type 2 osteoporosis, aging). This classification of the pathology allowed to establish therapeutic protocols more and more specific and tailored.

Figure 1. Multiple osteoporotic non-traumatic fractures (CT scan).

DIAGNOSIS

Only one non-traumatic spinal fracture can be significant for diagnosis of osteoporosis (Figure 1). The National Osteoporosis Foundation determined that a non-traumatic spinal fracture is compatible with the diagnosis of osteoporosis and constitutes a valid indication for introducing a medical treatment in order to prevent further vertebral collapses.

PRINCIPLES OF TREATMENT IN OPEN SURGERY

Very different spinal pathological conditions may affect the osteoporotic spine. They consist mainly of: acute and subacute single or multiple fractures, permanent spinal instability, postural abnormalities and sagittal imbalance, spinal stenosis and/or radicular due to deformity. In presence of neurological symptoms, caused by spinal cord or radicular compression, open surgery is the only treatment able to solve the symptomatology. No percutaneous treatment is indicated for the resolution of neurological symptoms. In presence of deformity and in case of severe osteoporosis, the only open decompression is not the treatment of choice, because of the risk of further progression of the deformity and the consequent non-resolution of the symptoms. For these reasons stabilization and fusion with pedicle screws is often necessary. However, in case of severe osteoporosis, the risk of implant failure and new fractures of adjacent segments is very high. Bone quality is a crucial question when you practice a stabilization with pedicle screws and, in cases of severely osteoporotic spine, the overall failure rate of the implants reaches 12%. A further problem is that osteoporotic patients may be very old and affected by different pathologies and for this reason, hardly amenable to surgery. Several studies have analyzed the reasons for such a high failure rate of surgical treatment, seeking the causes and proposing solutions. The most frequent complications were divided into early: pull-out of the pedicle screws and pedicle fractures of stabilized levels and delayed: degeneration of adjacent segments and pseudoarthrosis. In particular, non-fusion occurs because the excessive osteoclast activity, in the osteoporotic patient, leading to a delay in the fusion. In this way the system undergoes too prolonged stresses over time, waiting for the fusion, greatly increasing the chances of failure. These problems concern the whole instrumented surgery. It is very important to know that, in the osteoporotic patient, revision surgery, performed in case of implant failure, presents even greater difficulties than the first surgery.

SURGICAL TREATMENT

Internal Fixation – Points of Fixation

The multiple points of fixation is a valuable strategy in case of patients with severe osteoporosis. In presence of kyphosis is recommended three levels cranial and three levels caudal fixation from the center of the deformity. It is mandatory never stop the fixation inside the kyphotic segment of the spine because the sagittal imbalance would overload the implant and would produce excessive stress in a bone with very low mineral density, leading

unavoidably to failure. For this reason, it is very important that: the apex point of fixation of each implant should be below the dorsal kyphosis or at the beginning of the thoracic kyphotic curve, at the level of the first dorsal vertebrae. Regarding the low lumbar spine stabilization, several authors recommend the extension of the construct at the level of the sacrum and the ileum, in order to reduce the risk of failure of the implant. In case of severe deformity, we should not look for the ideal correction of the deformity, as in non-osteoporotic patient, in order to reduce the stress on the system. Multiple points fixation may be performed with some different instrumentations: hooks, sublaminar wires and, more frequently, with pedicle screws. Such techniques can be combined; several studies in the literature demonstrate how the combination of hooks or sublaminar wires with pedicle screws, increase the pullout resistance of the screws up to the 100%. Similarly, the use of the cement is a valid option in order to increase the pullout resistance of the pedicle screws. Under clinical view there is no difference between the use of hooks/wires or the cement. However, under a biomechanical point of view, the cement would seem to increase the stress on the implant during rotation while hooks/wires during the translation.

Pedicle Screws Fixation and Augmentation Techniques

The insertion of cement to increase the strength of the pedicle screws inside the osteoporotic bone, is a very well described technique in the literature (Figure 2). However, the debate on the best strategy of the pedicle screws augmentation is still open. Probably, the combination of cemented pedicle screws and hooks or wires (to protect the adjacent segments) is today the best technique. Some authors state that is not possible to perform a very long fixation using the cement for each level, as in case of severe deformity, where it is possible to cement only the apical screws of the construct. The most widely used material is the polymethylmethacrylate (PMMA); other possibilities are bioactive ceramics and calcium phosphate. Several studies demonstrate that vertebral body augmentation by PMMA or other material, increase the pullout resistance of the screw (from 119% to 250%), in case of first surgery and/or revision.

Figure 2. Cemented fenestrated pedicle screws (xray).

Vertebroplasty may be also very useful to cement the adjacent vertebrae to the implant, in order to reduce the risk of junctional fractures. This procedure can be also performed after open surgery as a second percutaneous step. Some authors describe the vertebral body augmentation by kyphoplasty. Burval shows the superiority of this technique compared to the insertion of the cement through the pedicle screw. The main trouble in the vertebral body augmentation with cement is the difficult to remove and replace the implant in case of infection or any other complication.

Pedicle Screws

In case of severe osteoporosis, it is very important to choose the screws with the maximum allowed diameter. It has been demonstrated that screws with diameter greater than 7 mm reduce the risk of pullout. However, because of the poor quality of the bone, it is very easy to break the pedicle during screw insertion. This complication occurs in a percentage from 24% to 40% of cases. In order to solve this problem, Cook created the expandable screws. This screw keeps its diameter inside the pedicle and expands inside the vertebral body. However, in case of very elderly patients with severe osteoporosis, the strength of the screws is inevitably compromise by the bad quality of the bone, mainly in case of compression fractures.

One other typology of screw, available today, is the fenestrated screw with dual and quad thread. This screw has some peculiar proprieties very useful in case of severe osteoporosis. In particular, the characteristics of the thread double the number of contact points with the cortical wall of the pedicle, increases the resistance with axial pullout forces. The presence of fenestration only in the distal portion of the screw, allows for cement injection directly into the vertebral body and ensures that the cement does not flow back into the pedicle. The peculiarities of this screw allow to avoid the use of oversized screws that increase the risk of pedicle fractures.

ABSTRACT

Fractures are common injuries, and their management has evolved over the last 30 years with a greater propensity to treat fractures surgically. There have also been accompanying advances with a better understanding of the principles of bone healing and their implications on implant choice. The purpose of this chapter is to highlight the various surgical fixation devices available for the management of fractures and their underlying principles.

Keywords: fracture, healing, fixation, devices

INTRODUCTION

This chapter deals with the principles of fracture fixation in trauma and orthopaedics (Al-Rashid et al. 2010). Fractures are common injuries with an incidence of 3.6 fractures per 100 people per year. The lifetime fracture prevalence exceeds 50% in middle-aged men, and 40% in women over the age of 75 years (Donaldson et al. 2008). The management of fractures takes up the more time and resources in emergency theatres than any other type of injury (Tambe et al. 2005). This chapter aims to describe the principles of successful fracture management and how fractures heal. This is followed by a description of commonly used implants used for fracture repair and the biomechanical principles that guide their use.

SUCCESSFUL FRACTURE MANAGEMENT

Successful fracture management aims to achieve early fracture union without significant complications. It is important to restore patients to a pre-fracture level of function. Fractures need to be reduced to a satisfactory position if they are displaced significantly. Following this the fractures need to be held or stabilised in a satisfactory position to allow fracture healing. In most cases, fracture stabilisation could be achieved using non-operative measures e.g. plaster casts, slings or straps. In some cases however surgical fixation or prolonged periods of traction is needed to stabilise a fracture till union is achieved.

Surgical fixation of fracture fragments can give sufficient stability permitting immediate joint movement, earlier weight-bearing, shorter hospital stay and early return to work and other activities. Early active pain-free mobilisation enhances articular cartilage nutrition by the synovial fluid. It also allows a rapid return of normal blood supply to bone and soft tissues. Early weight-bearing decreases post-traumatic osteoporosis by restoring the equilibrium between bone resorption and bone formation. Surgical fixation prevents many of the disastrous sequelae associated with non-operative management of fractures with traction and its associated prolonged periods of immobility including pressure sores, infections and deep vein thromboses. It is these principles and findings that have shaped fracture fixation surgery over the last 30 years and seen a shift from non-operative management of these fractures to a greater propensity for surgical fixation (Broos & Sermon 2004). This has been promoted by a higher patient expectation and a desire for earlier return to activities of daily living, and facilitated by the design of better surgical devices for fracture fixation.

BONE HEALING

Depending on the biological and mechanical environment, potentially contributed to by the surgical fixation devices, bone can heal in two ways (Rahn 1987). The first is indirect bone healing, afforded by relative stability of the fixation device. This begins with haematoma and inflammation followed by callus formation that remodels into woven or lamellar bone. This is achieved by any device which holds the bone sufficiently to maintain length and prevent rotation and angular deformity, but still allowing a low level of displacement or micro-movement between fracture fragments thus providing a mechanical signal that stimulates the biological repair processes. Gross motion between fracture fragments leads to non-union and fibrocartilage tissue formation and should be avoided. Examples of fixation devices that provide relatively stable fixation include locked intramedullary nails, plates used as bridging plates and external fixators as discussed below.

The second method is direct bone healing, and is facilitated in an environment of absolute stability provided by the fixation device. This results from internal remodelling that bypasses callus formation and allows contact healing between two vascular bone surfaces. This can be achieved by a device that prevents fracture surfaces displacing under physiological load. This requires anatomical reduction and inter-fragmentary compression. Inter-fragmentary compression is best achieved by a lag screw, or for large, dense bones, compression plate fixation as discussed below. The design and use of various surgical fixation devices relies on an understanding of bone healing and the loads and forces they are subjected to.

DIFFERENT IMPLANTS USED IN FRACTURE FIXATION SURGERY

Fractures vary in their pattern, and bones vary in their size, structure and strength. As a result, a wide variety of fixation devices has been developed and continues to be developed. More recent implants are made of biocompatible materials and have a low profile resulting in reduced rates of soft tissue irritation. They can also be contoured to suit individual anatomy. The successful application of these fixation devices lies in a thorough understanding of the individual fracture personality, its biology and the underpinning biomechanics of the fixation device.

In addition to the understanding of how the mechanical environment of fracture fixation shapes fracture healing, it is crucial to recognise how the type of implant affects the biology of the fracture healing. It is thought that adequate blood supply to bony fragments of the fracture through the soft tissues is of utmost importance for fracture healing to progress (Rüedi & Murphy 2000). Hence any fracture fixation surgery which further violates this blood supply in already tenuous devascularised bony fragments will adversely affect healing. This is one of the main reasons why external fixation is preferred where there is significant soft tissue damage, rather than internal fixation and its associated soft tissue dissection.

Any fixation device used in trauma surgery must be biologically inert, and not give rise to toxic reactions or local inflammatory changes (Gotman 1997). It is also important to avoid any electrolytic degradation and corrosion by avoiding implant of different materials at the same site. Metals currently used include stainless steel (316L), alloys of chromium, cobalt and molybdenum, and titanium (Ti-6Al-4V). Corrosion resistance of these materials relies on their passivation by a thin surface layer of oxide. Stainless steel is the least corrosion resistant and less inert, but easier to machine and cheaper. The cobalt chrome alloys are biologically very inert but are difficult to machine adding to their cost. Titanium has the favourable combination of high strength, light weight, high fatigue strength and low modulus of elasticity, and is biomechanically closer to bone than 316L stainless steel. This allows production of thinner plates and stronger intra-medullary nails.

More recently there has been interest in the use of biodegradable polymers e.g. polylactic acid (Hughes 2006). These have the advantage of being more flexible resulting in greater weight-bearing by the bone thus avoiding stress shielding, and they do not need to be removed. Their disadvantages include limited strength and risk of adverse biological response, and these have hindered the more widespread use of these materials.

Numerous devices are available for the fixation of fractures and these include wires, pins, screws, plates, intra-medullary nails and external fixators (Malik et al. 2009, Khan et al. 2010, Dheerendra et al. 2011, Haughton et al. 2012).

1. Pins

There is a variety of pins used in trauma surgery for the fixation of fractures (Kurup et al. 2008, Yosri et al. 2012). The pins may be smooth or threaded, and are available in a number of sizes. Threaded pins provide additional stability, as they minimise sliding of bone fragments, but are also more difficult to take out. Among the most commonly used are Kirschner wires, commonly called K-wires, and Steinman pins.

K-wires can be used to hold fragments of bone prior to rigid fixation, and for percutaneous pinning of small bone fractures. They are commonly used in hand and wrist fractures (Malik et al. 2009). At least two wires should be used and they should not be parallel (Figure 1).

Figure 1. Antero-posterior and lateral radiograph of a distal radial fracture at the wrist stabilised with two Kirschner wires and a back-slab plaster.

They lack sufficient mechanical stability for use as the primary fixation device in long weight bearing bones. Steinman pins, are commonly used to apply skeletal traction, and are attached to traction devices.

2. Wires

In combination with pins or screws, wires can be used to create a tension band that converts distractive muscular forces to compressive forces at the fracture site. Wires are frequently used for the fixation of olecranon (Figure 2) and patella fractures. They are also used to reattach bone fragments e.g. greater trochanter or olecranon after elective osteotomies (Nork et al. 2001). The use of tension band wires requires tightening to achieve equal tension, and this can result in wire breakage or cut-through of bone. Many companies now manufacture wire tensioning and twisting instruments. The use of wires also relies on the making of holes for passing the wires that can be associated with complications. Wires in the form of cerclage wires, are also used to deal with periprosthetic fractures, for fixation of bone fragments and plate onto bone.

Figure 2. Antero-posterior and lateral radiograph of an olecranon fracture at the elbow fixed with tension band wiring.

3. Screws

A variety of screws are used in trauma surgery (Mudgal & Jupiter 2006). It is a device which converts rotational or torsional forces to compressive forces. Screws can be cancellous or cortical, self tapping or non-tapping, partial or fully threaded, locking or non-locking. They can be of different sizes from 1.5mm to 8.0 mm, based on the site of their application. The screw essentially consists of the screw head, the bulbous end and the part engaged by the screwdriver, and the shank or core, which can be of variable diameter and sizes. The distance between the threads is called the pitch. The factors that affect the holding power of the screw are its outer thread diameter, thread configuration and thread length. The choice of screw depends on the type of bone, fracture configuration, associated implant used and surgeon's preference.

They can be used in isolation to hold two fragments of bone together. If screws are used in isolation, an attempt should be made to insert them perpendicular to the fracture line to avoid shear forces (Figure 3). If the fixation relies on the lag principle, the hole in the proximal bone fragment is over-drilled to avoid engagement of the threads and this allows compression between the distal fragment engaging the screw threads and the screw head on the proximal fragment. Screws are commonly used in combination with plates (Figure 4) and nails or rods (Figure 5). Screw can be inserted using a torque screwdriver that allows a controlled and constant force to be applied.

Figure 3. Antero-posterior and lateral radiograph of an intra-capsular fracture of the hip fixed with three cannulated screws.

Figure 4. Antero-posterior and lateral radiograph of a radial and ulnar fracture of the forearm fixed with plates and screws.

Figure 5. Antero-posterior and lateral radiograph of a tibial fracture of the lower leg fixed with an intra-medullary nail and locked with proximal and distal screws for rotary and axial stability.

4. Plates

Plates have screw holes that are counter-sunk to avoid prominence of the screw head. A variety of plates is available that can be used for fracture fixation to provide both relative stability and absolute stability (Egol et al. 2004). The way a plate is used determines its mechanical function. In the neutralisation mode, the plate functions to reduce the forces on an inter-fragmentary compression or lag screw. In the buttress mode, the plate acts to support the fracture fragment preventing displacement from forces. Plates can be used as bridging plates to span gaps where bone has been lost due to trauma or disease. In the compression mode, the screws are inserted offset from the centre and on tightening the bone fragments move closer together providing inter-fragmentary compression. Locking plates have threaded holes for the screw head to engage in and provide more durable fixation that is better for osteoporotic bone (Cornell et al. 2003). These locking plate systems avoid the need for bicortical fixation. The majority of these plates are made of stainless steel or titanium.

A plate is considered to provide relative stability if it allows appreciable inter-fragmentary movement under functional load. Fracture healing under conditions of relative stability takes place by callus formation. Bridging of the fracture with a stiff splint reduces mobility of the fracture fragments, which allows minimal displacement under functional load. A plate that provides rigid fixation, e.g. with inter-fragmentary compression, provides absolute stability of the fracture fragments diminishes the strain at the fracture site and allows direct healing without callus formation.

Rigid fracture fixation with plates and screws still has an important place and is desirable for fractures that involve an articular surface. Articular fractures require exact anatomic reduction and stable fixation to avoid development of abundant callus. This is important because incongruity of the joint surface and presence of callus formation at the articular surface lead to patient discomfort and often development of early and progressive osteoarthritis (Dirschl et al. 2004).

The use of plates does rely on a significant exposure that can compromise blood supply that is already disrupted from the fracture and possible associated soft tissue injury. If a plate is in total contact with a bone surface, it can act like a plug and stop radial perfusion, leading to necrosis of the bone. If the bone plate contact is reduced, as is increasingly the case with

the newly developed plates, there will be less disruption to this radial perfusion of the bony fragment (Miclau & Martin 1997).

5. Intra-Medullary Nails

Intra-medullary devices act as an internal splint to stabilise long bone fractures (Hohaus et al. 2008) as shown in Figure 5. They neutralise varus and valgus forces, and allow axial compression. This can result in shortening in comminuted fracture if the nail is not locked. The locking option of a nail allows better rotational control. Nails can be solid or hollow, slotted or non-slotted. Solid nails are stiffer in bending, although these properties may be altered by changing the wall thickness. Reaming of bone allows better fixation of the nail and improves the transfer of load from the bone to the nail and stability (Pape & Giannoudis 2007). Slotted nails have less torsional stiffness than non-slotted ones.

Stiffness and strength are related to the diameter of the nail, and the strength of a nail determines its resistance to fatigue failure. The bending rigidity of the nail is proportional to the radius to the fourth power thus one large nail is stiffer than multiple smaller nails.

6. External Fixation

Another method of fracture stabilisation is with an external fixation (Ziran et al. 2008) as shown in Figure 6. This involves percutaneously placed transosseous pins and/or wires secured to external scaffolding in the form of bars and rings providing support and stabilising a fractured bone. There are a large number of variables that determine the stability provided by the external fixator construct and these include the number, location and diameter of the pins and connecting rods as well as the orientation of the construct.

Figure 6. Antero-posterior and lateral radiograph of a tibial fracture of the lower leg fixed with an external-fixator.

External fixators cause less disruption to the soft tissues, and better preserve the blood supply to bone and periosteum (Claes et al. 1999). This makes fixators a useful tool in open fractures enabling satisfactory soft tissue management in the acute trauma setting with skin

contusions and open wounds. They are also useful in peri-articular fractures as they allow restoration of the articular surface by ligamentotaxis and early mobilisation (Khan & Fahmy 2006, Bhamra et al. 2012). One major complication with the use external fixators is associated pin site infections. External fixators have a wide scope of use in trauma surgery as quick, life saving temporary fracture stabilisation devices in the multiple trauma patients.

CONCLUSION

Fractures are common injuries and there has been a greater trend over the last few years from non-operative management with traction to early surgical fixation. There are a number of fracture fixation devices available for the fixation of fractures and these devices could be used in a number of different ways depending on the nature of the fracture and associated injuries. Bone can heal in two ways; the first is indirect bone healing afforded by relative stability of locked intra-medullary nails, bridging plates and external fixators. The second method of bone healing is direct bone healing, and is facilitated in an environment of absolute stability provided by lag screws and compression plating.

Chapter 385

SURGERY IN ELDERLY PATIENTS WITH HIP FRACTURES

J. White, P. Smitham and W. S. Khan*

University College London Institute of Orthopaedic and Musculoskeletal Sciences,
Royal National Orthopaedic Hospital, Stanmore, Middlesex, UK

ABSTRACT

Hip fracture is a major cause of morbidity, mortality and loss of independence for the elderly. Surgical fixation of the fractured hip remains the standard of care to allow for early mobilisation and a return to independence. Operative management in this population carries its own set of problems. The altered physiological state of the older person, often coupled with significant co-morbidity, can present challenges for the anaesthetist, the surgeon and the rest of the perioperative team. This chapter provides an evidence-based review of these important perioperative factors associated with hip fractures in the older person and their management.

Keywords: hip fractures, elderly, co-morbidity, pain, venous thromboemboli

INTRODUCTION

This chapter discusses the evidence for managing hip fractures in elderly patients (White et al. 2011). Hip fractures are frequent injuries amongst older patients with osteoporosis and account for about 76,000 cases in the UK per year according to the National Hip Fracture Database (NHFD 2010). A review that examined the extensive hip fracture literature published in the English language between 1980 and 2009 concerning hip fracture prevalence trends suggested that hip fractures will remain a serious global health issue (Marks 2010). Hip fractures are a major cause of morbidity, mortality and loss of independence in the elderly.

These fractures pose a major public healthcare burden and continue to consume large portions of healthcare resources.

Surgical fixation of fractured hips remains the standard of care to allow early mobilisation and a return to independence. Timely surgery limits the period of recumbence and helps to prevent pressure sores, urinary tract infections, deep vein thrombosis and pulmonary complications including atelectases, pneumonia and pulmonary emboli. Surgical intervention is considered superior in medically-fit elderly patients (Parker et al. 2000, Beaupre et al. 2005), and ideally this should be completed within 48 hours for the majority of patients with hip fracture (Egol & Strauss 2009). Even in the absence of co-morbidity, the altered physiological state of the older person can present challenges for the anaesthetist and the rest of the perioperative team. Operative management in this population carries its own set of problems and implications, and these are discussed below.

Fractures of the neck of femur could be divided into extracapsular and intracapsular fractures. Extracapsular fractures are generally treated with fixation using a dynamic hip screw or intramedullary nailing. Although undisplaced intracapsular fractures are also generally treated with fixation using cannulated screws, there is controversy regarding the optimal management of displaced intraarticular fractures. Although most elderly patients with displaced intraarticular fractures are managed with a hemiarthroplasty and do well, there is increasing evidence to suggest that a total hip replacement improves patient functional outcomes for healthy, independent, elderly patients compared with hemiarthroplasty and should be considered as the treatment of choice for these patients as it is more predictable, durable and cost-effective in the longer-term (Schmidt et al. 2005, Malik et al. 2009, Dheerendra et al. 2010, Lowe et al. 2010). A detailed discussion on the surgical management of these fractures is beyond the scope of this chapter.

PREOPERATIVE MEDICAL CONSIDERATIONS

The key difference between elderly patients and their younger contemporaries is a loss of functional reserve and a general decline in organ function (Muravchick 2000). Although age is not an independent risk factor for post-operative complications, the perioperative period is filled with increased risk secondary to the higher incidence of co-existing disease in the elderly. Older patients may present with an array of co-morbidities involving any organ system and these must be evaluated and optimised prior to surgery to improve the post-operative outcome. This highlights the crucial roles played by both anaesthetists and geriatricians in the perioperative management of this challenging patient population.

The risk of postoperative complications in the elderly hip fracture patient is proportional to the number of co-morbidities present. Roche et al. (2005), in a prospective cohort study of 2,448 geriatric patients with hip fracture, evaluated the relationship between preoperative co-morbidity and the risk of postoperative complications and mortality. The authors found that the presence of three or more preoperative co-morbidities is the strongest predictor of increased mortality at 30 days postoperatively, followed by respiratory disease and malignancy. The most common postoperative complications were chest infection (9%) and cardiac failure (5%). These findings underline the importance of effective medical assessment and optimisation in the perioperative period.

A number of studies have sought to identify specific co-morbidities predictive of increased postoperative mortality. Mortality data at 30 days (Nettleman et al. 1996), six months (de Luise et al. 2008) and one year post-injury (Penrod et al. 2008) have identified a history of congestive cardiac failure (CCF), chronic obstructive pulmonary disease (COPD) and and/or malignancy as strong positive predictors. Nettleman et al. (1996), in a retrospective analysis of 390 elderly patients with hip fracture, found that 63% of inpatient mortalities were cardiovascular in nature.

THE AMERICAN ASSOCIATION OF ANAESTHETISTS GRADING

The American Society of Anaesthetists (ASA) developed a grading system (I to V) to classify patients according to their physical status, thus serving as an indicator of anaesthetic and surgical risk. A normal, healthy individual with minimal risk is deemed ASA class I, whereas a moribund patient who is not expected to survive 24 hours regardless of surgery is designated ASA class V. The majority of elderly patients will be ASA class II or greater (AAGBI 2001).

The ASA score is a useful predictor of long term mortality after hip fracture (Michel et al. 2002, Richmond et al. 2003, Bjorgul et al. 2010). In a prospective study of 1,635 patients with hip fracture, Bjorgul et al. (2010) demonstrated that survival rates vary significantly between ASA classes. Over a five to ten year period postoperatively, survival for ASA I was 8.5 years versus only 1.6 years for ASA IV. Use of the ASA classification to predict postoperative mortality risk can be further enhanced by complementing it with the Short Portable Mental Status Questionnaire (SPMSQ) for assessing cognitive function. Soderqvist et al. (2009), in a prospective cohort study of 1,944 patients aged 66 or older, revealed that the combination of ASA score and SPMSQ provides greater information about survival times compared with the ASA score alone.

In addition to mortality the risk of medical complications can be predicted using the ASA class. In a retrospective analysis of 197 elderly patients with hip fracture, Donegan et al. (2010) reported that medical complications were more common in those with ASA classes III and IV compared with ASA class II. Furthermore, patients classed as ASA IV were over seven times more likely to have medical complications compared with those in class II. These complications are numerous, and in a retrospective study of 8,930 patients aged 60 or over with hip fracture, Lawrence et al. (2002) listed cardiac and pulmonary complications as most frequent (8% and 4% respectively). Other complications included gastrointestinal bleeding (2%), venous thromboembolism (1%), and transient ischaemic attack or stroke (1%). In another series of 1,010 patients evaluated by Ranhoff et al. (2010), the most common complications were anaemia requiring transfusion, delirium and urinary tract infections.

SURGICAL COMPLICATIONS

Surgical complications include superficial wound infections, deep joint infections, hip dislocations, periprosthetic fractures, failure of fracture fixation, neurovascular injuries and leg length discrepancies (Hall et al. 2009). Most of these complications will need further surgical interventions. Although no study has determined a link between age and

complications, the number of co-morbidities is proportional to the risk of postoperative complications (Roche et al. 2005) and elderly hip fracture patients are more likely to have co-morbidities. The reduced functional reserve and general decline in organ function seen in the elderly patients (Muravchick 2000) makes it more difficult for them to cope with the increased physiological demands of the complication and the possible surgical intervention that it may require.

POSTOPERATIVE PAIN CONTROL

The provision of adequate analgesia for hip fracture patients is essential, not only to allow for effective ambulation postoperatively, but also to help prevent complications. The pain induced by trauma and surgery leads to decreased mobility, and this in turn leads to reduced respiratory effort causing atelectasis and pneumonia. Decreased mobility also predisposes to urinary tract infections, deep vein thromboses and pulmonary emboli. Poor postoperative pain control can lead to a vicious cycle in which the pain itself is compounded by the patient's own anxieties, thus limiting progress even further.

Although some evidence exists regarding the most appropriate analgesia for patients with hip fracture, better analgesic control for the elderly need to be discovered (Beaupre et al. 2005). Poorly controlled pain however, increases the length of hospital stay, delays mobilisation, and reduces long-term functional ability (Morrison et al. 2003). It is likely that complications arise secondary to impaired cognition, medical co-morbidities, and altered drug metabolism and pharmacokinetics. These factors make effective pain control in the older population far more complex than their younger counterparts.

Acutely, postoperative pain management with intravenous morphine can be safely achieved using the same protocol as for younger patients. There appears to be no difference in the incidence of morphine-related complications or sedation (Aubrun et al. 2002). Several days postoperatively however, opioid requirements amongst elderly patients drop in comparison (Gagliese et al. 2000). It is important that regular pain assessments are made to allow for adequate dosing adjustments, in addition to a baseline assessment upon arrival to hospital. Furthermore, special consideration must be given to cognitively-impaired patients, whose pain control is often suboptimal due to self-reporting of less pain. Behavioural pain indicators do not however differ between cognitively-impaired and cognitively-intact patients, supporting the use of behavioural assessments in the cognitively-impaired (Horgas et al. 2009). Another strategy to ameliorate this may be the adoption a standardised protocol for pain management (Adunsky et al. 2002).

Regional analgesia via the epidural route may provide a novel technique for managing acute postoperative pain in elderly hip fracture patients, although more research is needed. Foss et al. (2005) examined the effect of four days postoperative epidural infusion of bupivacaine and morphine versus placebo in 60 elderly hip fracture patients. Epidural analgesia was found to be significantly superior in managing postoperative pain during all basic physical functions compared with controls. Despite the improved pain relief, there was no significant difference in scores for recovery of physical independence. These findings demonstrate that epidural analgesia provides enhanced pain control over standard regimens,

but further studies are needed to elicit whether this improvement translates into enhanced recovery.

PRESSURE ULCER PREVENTION

The development of pressure sores after hip surgery is a common occurrence, with a reported incidence ranging from 9% to 55% (Gunningsberg et al. 2000, Baumgarten et al. 2003). It carries a great burden of morbidity as patients that develop pressure ulcers are at increased risk of developing nosocomial infections and other hospital complications, as well as enduring a significantly longer hospital stay (Allman et al. 1999). The assessment and management of a pressure ulcer requires a systematic, comprehensive and multidisciplinary approach. Assessment of an elderly hip fracture patient includes the patient's comorbidities, functional state, nutritional status, and degree of social and emotional support (Jaul 2010). Vigilant nursing care can reduce this risk, through visual inspection, frequent turning, and the application of topical preparations. Furthermore, the implementation of heel protection and pressure-relieving mattresses can provide additional benefit. In a prospective randomised controlled trial assessing the benefits of an interface pressure-decreasing mattress, Hofman et al. (1994) found that the incidence and severity of pressure ulcers were significantly reduced compared with a standard hospital mattress (24% versus 68%).

Currently there is no research evidence that high-tech pressure-relieving mattresses are more effective than low-tech foam mattresses for the prevention of pressure ulcers. There is also a lack of evidence regarding the benefit of heel protection devices. Professional consensus recommends their use, but further research is needed.

VENOUS THROMBOEMBOLISM PREVENTION

Hip fracture is a major risk factor for venous thromboembolism (VTE) throughout the perioperative period. Other significant risk factors include malignancy, coagulopathy, immobility, previous VTE, obesity, stroke, atherosclerosis, and ASA grade ≥ 3 (Beksac et al. 2006). Advanced age is weakly associated with the development of VTE (Abad Rico et al. 2010). Incidence rates for deep vein thromboses range from 36% to 60% (Ennis 2003), whilst those of pulmonary embolism range from 4% to 24% (Egol and Strauss 2009). Fatal pulmonary emboli occur in 1% to 13% of cases (Ennis 2003).

Despite extensive research on an optimal thromboprophylaxis strategy, there remains no agreement on a standard protocol (Chahal et al. 2013). The Pulmonary Embolism Prevention (PEP) trial (2000) assessed the effect of aspirin versus placebo for VTE prophylaxis in 13,365 patients with hip fracture. Treatment with aspirin reduced the risk of both symptomatic deep vein thromboses and pulmonary emboli when compared with placebo (29% and 43% respectively). There was an increased transfusion requirement in patients assigned aspirin, however mortalities due to bleeding were comparable between study groups. Based on the findings, the authors concluded that treatment with aspirin decreases the incidence of deep vein thromboses and pulmonary emboli by a third perioperatively and should be used routinely in patients with hip fracture.

A retrospective study by Ennis (2003) of 1,000 consecutive hip fractures compared the use of aspirin with the low-molecular-weight heparin (LMWH), enoxaparin. Although there was no significant difference in deep vein thrombosis rates between the treatment groups, there was one case of fatal pulmonary embolism in those treated with aspirin and no pulmonary emboli recorded with enoxaparin. Considering its short half-life, predictability and favourable safety profile, the author concluded that enoxaparin, and thus LMWH, was an ideal form of thromboprophylaxis.

A total of 32 trials covering 3,614 adult hip fracture cases have shown that unfractionated heparin and LMWH protect against VTE (Handoll et al. 2002, Eriksson & Lassen 2003). In a Cochrane review by Handoll et al. (2002) however, there was insufficient data to confirm a protective effect against pulmonary emboli. No significant differences were established between unfractionated heparin and LMWH. Eriksson & Lassen (2003) found that fondaparinux (factor Xa inhibitor) conferred a relative reduction in the risk of VTE (including pulmonary emboli) of 96% when compared with placebo. The incidence of symptomatic VTE was also found to be significantly lower in patients treated with fondaparinux and there was no increase in the incidence of clinically significant bleeding.

Turpie et al. (2002) reported a meta-analysis of four randomised, double-blind trials comparing the prophylactic effects of fondaparinux and enoxaparin in 7,344 cases of hip fracture. Fondaparinux was shown to confer a significantly greater protective effect against VTE than enoxaparin, with an odds reduction of 55%. It was also shown to significantly reduce the incidence of proximal deep vein thromboses with a reduction of 57%. The risk of clinically relevant bleeding was low and did not differ significantly between the treatment groups. In a retrospective study by Shorr et al. (2007) of 144,806 patients who had undergone major orthopaedic surgery, including that for hip fracture, the benefits of fondaparinux were further clarified. Patients receiving fondaparinux experienced fewer VTE events (1.5%) compared to enoxaparin (2.1%), dalteparin (2.1%) and unfractionated heparin (4.2%).

Post-discharge, there remains a risk of delayed thromboembolic events, thus justifying the need for extended thromboprophylaxis (Anand & Buch 2007). Prolonged treatment with fondaparinux over a 4-week period can reduce the risk of DVT by 96% and the risk of symptomatic VTE by 89% compared with perioperative (1-week) treatment (Kwong 2004). The American College of Chest Physicians recommends the routine use of fondaparinux, LMWH, or unfractionated heparin for patients undergoing hip fracture surgery. Their guidelines also recommend against the use of aspirin alone for thromboprophylaxis and encourage the use of physical methods of anticoagulation for patients with a high bleeding risk or as an adjunct to chemoprophylaxis (Geerts et al. 2008).

POSTOPERATIVE CONFUSION/DELIRIUM

Postoperative delirium is characterised by a disturbance of consciousness and temporary abnormalities in cognition and perception. It is a common problem in the elderly hip fracture patient with a postoperative incidence ranging from 5% to 61% (Edelstein et al. 2004, Gustafson et al. 1988). Risk factors for delirium include advanced age, pre-fracture cognitive and functional impairment, pre-existing cerebrovascular and other brain diseases, indoor injury, communication difficulties and social isolation (Duppils & Wikblad 2001, Juliebo et

al. 2009). Precipitating factors for delirium comprise perioperative falls in blood pressure, postoperative infections and malnutrition (Edlund et al. 2001). Perioperative risk factors associated with postoperative delirium include intraoperative blood loss, electrolyte abnormalities and a postoperative haematocrit <30% (Mercantonio et al. 1998). Neither intraoperative haemodynamic instability nor route of anaesthesia is associated with increased postoperative delirium (Mercantonio et al. 1998). A randomised controlled trial by Sieber (2009) did demonstrate however that the depth of sedation achieved with propofol during spinal anaesthesia does influence the subsequent development of delirium. In the trial, 114 individuals were randomised and the results showed that there were far fewer cases of delirium in the light sedation group versus the deep group (19% versus 40% respectively). The authors concluded that limiting the depth of sedation during spinal anaesthesia is a safe, effective and economical and should be widely instituted.

Unfortunately, postoperative delirium has received little attention in the perioperative literature, despite its considerable morbidity and mortality. Over two decades ago, it had shown to significantly increase the length of hospital stay and postoperative complications such as urinary incontinence, feeding difficulties and pressure sores (Gustafson et al. 1988). Patients experience reduced ambulation and rehabilitation, with a decline in their activities of daily living, prefracture walking level and ultimately their independence. Finally, patients suffer an increased rate of mortality or are placed into a nursing home (Gustafson et al. 1988, Mercantonio et al. 2001, Edelstein et al. 2004).

Management strategies towards postoperative delirium are therefore necessary to prevent and/or lessen the impact on patient outcomes. Careful and frequent assessment of a patient's mental status and cognitive function are important as is addressing any risk factors present. Precipitating factors need to be avoided and if delirium does present itself, treatment needs to focus on supportive care and identifying the underlying causes. Specific measures include adequate postoperative analgesia, careful drug selection and management within a multidisciplinary framework. Mercantonio et al. (2001) conducted a randomised controlled trial assessing the effects of regular geriatrics input on postoperative delirium in 126 elderly hip fracture patients. Geriatrics consultation was shown to significantly decrease the incidence of postoperative delirium by a third, with a relative risk of 0.64. There was an even greater reduction in cases of severe delirium, although length of stay did not vary significantly between intervention groups. In a similar study by Lundstrom et al. (2007), postoperative care on either an orthopaedic ward or geriatric ward was compared in 199 patients. Less patients treated on the geriatric ward developed delirium, and if so, their delirium lasted for a shorter period of time. Furthermore, intervention patients developed fewer complications such as pressure ulcers, nutritional deficits, urinary tract infections, sleeping problems and falls.

CONCLUSION

Based on the literature we have reviewed, hip fractures are common injuries and are a major cause of morbidity, mortality and loss of independence for the elderly. Although surgical fixation of the fractured hips remains the standard of care, operative management carries its own set of problems. The altered physiological state of the older person, often

coupled with significant co-morbidity, can present challenges for the anaesthetist and the rest of the perioperative team. It is important that an evidence-based approach is utilised to help ensure the patient, who has been optimised perioperatively, has appropriate management of pain, pressure ulcers, venous thromboemboli, delirium and confusion. The appropriate assessment and evidence-based management of these patients should lead to an improved outcome.

Chapter 386

ARTHROSCOPIC KNEE SURGERY: AN EVIDENCE-BASED PRACTICE

***Christopher Onyema, Emeka Oragui,
Jonathan White and Wasim S. Khan****

University College London Institute of Orthopaedics and Musculoskeletal Sciences,
Royal National Orthopaedic Hospital, Stanmore, London, UK

ABSTRACT

Knee arthroscopy is a minimally-invasive technique that allows intra-articular assessment and treatment of knee joint pathology. It has proven benefits of reduced patient morbidity, earlier recovery and mobilisation, and it is cost-effective. In this chapter we review the anatomy of the knee joint, indications and contra-indications to knee arthroscopic use, and consider the main techniques of knee arthroscopy including types of anaesthetic, prophylactic antibiotics, theatre setup and arthroscopic portals, and post-operative care.

Keywords: Knee; arthroscopy; evidence-based practice; minimally invasive surgery (MIS)

In this chapter we review the evidence base behind arthroscopic knee surgery (Onyema et al 2011). Arthroscopy of the knee is the most common operative procedure in orthopaedic surgery today. Like all arthroscopic procedures, it delivers a minimally invasive approach to orthopaedic operations that previously necessitated open surgery. The basic principle involves the insertion of a camera and associated equipment through small portals in the skin to allow intra-articular evaluation and treatment of pathology. Professor Kenji Takagi of Tokyo has traditionally been cited as having performed the first arthroscopic assessment of the knee in 1919 although it may be that the Danish physician Severin Nordentoft actually pioneered the technique seven years earlier. The technique became an established feature of orthopaedic practice during the 1970s, and today surgeons can perform an array of complex intra-articular

* Corresponding Author's Email: wasimkhan@doctors.org.uk; Fax: +44 (0) 1707 655059.

operations through small incisions (Katz & Gomoll 2007). Knee arthroscopy is used to perform many procedures that previously necessitated an open procedure such as simple meniscectomies, ligament reconstruction and cartilage restoration.

There are many advantages of arthroscopic surgery over traditional open surgery. The minimally invasive technique results in less trauma to the patient, less post-operative pain and less blood loss. Patients recover faster and can quickly return to their normal daily activities. A day surgery arthroscopic procedure is more readily accepted by patients than an in-patient arthrotomy and may facilitate earlier intervention. Cosmetically-speaking, smaller skin scars are more appealing. An economic benefit is provided as patients spend less time in hospital, can quickly return to work, and overall, the procedure is less expensive compared to open operations.

ARTHROSCOPIC KNEE ANATOMY

The knee joint comprises articulations between the medial and lateral compartments of the distal femur and proximal tibia as well as an articulation between the patella and the anterior aspect of the distal femur, which forms the third, patellofemoral compartment. The surfaces of these bones are lined with articular cartilage and in addition two crescent-shaped fibro-cartilaginous pads called menisci lie between the femoral and tibial compartments and are joined by a transverse inter-meniscal ligament that connects them anteriorly. These menisci protect articular surfaces by providing lubrication and reducing friction. They may also have a role in providing nutrition to tissues (Katz 2007).

The peripheral part of the meniscus is vascular and DeHaven (1990) suggested that tears in the peripheral 3 mm are amenable to repair (Koval & Zuckerman 2004), whereas tears more than 5 mm from the menisco-capsular aspect are avascular with little or no potential for healing or repair.

The knee joint is stabilised by ligaments around the knee. These include the medial and lateral collateral ligaments which can be palpated at the joint line and resist varus and valgus strain respectively. The anterior cruciate ligaments (ACL) and posterior cruciate ligaments (PCL) lie within the joint and resist displacement of the tibia on the femur in an anterior or posterior direction respectively. The fibrous capsule contributes to the stability of the joint. The knee is also supported by several muscles that include the quadriceps and the hamstrings (Koval & Zuckerman 2004).

INDICATIONS AND CONTRA-INDICATIONS TO KNEE ARTHROSCOPY

Knee arthroscopy may be diagnostic or therapeutic, and is indicated when there is no other way to confirm the diagnosis, or the lesion is amenable to arthroscopic surgery and no easier technique to treat the pathology exists. The final decision on whether to perform an elective knee arthroscopy or not usually relies upon symptoms and disabilities that negatively impact on the quality of a patient's life but may be hard to quantify (DeHaven 1990). The use of knee arthroscopy has been demonstrated for diagnosis and treatment of intra-articular

lesions, loose bodies, meniscal tears, osteoarthritis, cartilage repair, ACL reconstruction, synovectomy and plicectomy, unexplained knee pain, intra-articular tumours, painful knee after total knee replacement, pyogenic arthritis, and arthro-fibrosis (Marx 2008).

Only a few contraindications for knee arthroscopy exist. These include localised soft tissue infection where the insertion of the equipment into the knee joint may introduce infection into the joint and cause overt sepsis. Infection in the joint itself is not a contraindication, and in such cases arthroscopic techniques may be employed for debridement and drainage.

Severe degenerative joint diseases resulting in stiffness or ankylosis of the knee may prohibit manoeuvring of the arthroscope within the various compartments and access may be difficult. It may also be difficult to operate on any patient with a recent haemarthrosis as visualisation may be compromised. Training and technical ability also limits the procedures that may be performed by any knee surgeon (Noble 1992).

A thorough evaluation of the patient before the procedure is mandatory and should include a relevant history, examination and appropriate imaging. Magnetic resonance imaging (MRI) is useful as it has been shown to be reliable for the exclusion of intraarticular lesions, thus reducing the number of unnecessary arthroscopies (Friemert 2004). During the operation, all necessary imaging should be made available (Jackson 1972).

ANAESTHESIA

Arthroscopic knee surgery can be performed with general, regional or local anaesthesia, each having its own advantages and disadvantages. The anaesthetic technique(s) used will depend on the preferences of the anaesthetist, patient and operating surgeon, as well as local guidelines.

1. General Anaesthetic

General anaesthesia has remained the most common modality for knee arthroscopy. This technique puts the patient to sleep, allowing complete muscle relaxation for the entire procedure and is a good choice for very young or anxious patients. However, there are associated risks of allergic/ anaphylactic reactions to the anaesthetic agents and the risk associated with intubation and ventilation during general anaesthesia (Dandy 1997). In the anaesthetic room, a laryngeal mask airway is commonly used. Before starting the procedure the portal sites may be injected with a local anaesthetic as this has been shown to reduce post-operative pain and opioid requirements (Buckenmaier 2002).

2. Spinal Anaesthetic

Spinal anaesthesia provides good single-injection anaesthesia for knee arthroscopy. It is preferred for lower limb orthopaedic surgery because of its reliability and simplicity. It

permits the patient to be awake during the procedure if desired. Other advantages include a rapid onset, high reliability, and a reduction in the time that the patient spends in post-anaesthesia recovery and facilitates early hospital discharge. Low dose, short-acting agents such as lidocaine have considerable benefits over long-acting agents in terms of recovery and home discharge. Disadvantages include the small risk of spinal headache despite using newer spinal needles, and the possibility of a difficult spinal puncture (McKeon et al 2009).

3. Local Anaesthetic

Although not commonly practiced in the UK or US, knee arthroscopy under local anaesthesia has been shown to be reliable and safe with appropriate case selection by an experienced anaesthetist. Evidence for its efficacy has been demonstrated in Hong Kong, Japan and Sweden (Law et al 2009, Jacobsen et al 2000, Yoshiya et al 1988). The disadvantages are that this method of anaesthesia may limit tourniquet use, and the patient's tolerance to movement of the limb may limit the amount of forceful manipulation that can be achieved.

In some cases, conversion to general anaesthesia is required. Local anaesthesia is cost-effective, allows for a quicker recovery and shorter hospital stay (O'Donnell BD & Iohom 2008). Nevertheless, the use of arthroscopy under local anaesthesia will depend on surgeon preference and local practice.

The local anaesthetic should be injected into the portal sites and joint itself, with most of the agent being injected into the subcutaneous layer. Successful intra-articular injection can be confirmed by a positive patellar tap and bulging from the medial gutter. Introduction of the agent into the subcapsular layer should be avoided as this will push the fat pad into the joint, hindering visualisation in the initial stages. A twenty minute waiting interval should be given after the injection to allow for onset of action of the agent. Sedatives can also be given for anxious or apprehensive patients.

PROPHYLACTIC ANTIBIOTICS

Prophylactic antibiotics are not routinely used for knee arthroscopy because the procedure is considered clean. This is supported by the low rate of post-operative infection reported in the literature. The use of antibiotics also increases costs and introduces a risk of allergic reactions and the development of antibiotic resistant organisms (Law et al 2009, Allum 2002). In a study of 2,780 arthroscopic meniscectomies Bert et al (2007) showed that there was no value in administering antibiotics. They reported infection rates of 0.15% when prophylactic antibiotics were administered compared to 0.16% in patients who received no antibiotics ($P = 0.59$).

Complex procedures of long duration or those that involve the use of implants may require antibiotics. Patients who have a high risk of infection and those with conditions such as diabetes, skin and immunological disorders should also be considered for prophylactic antibiotics (Allum 2002).

THEATRE SETUP

1. Skin Preparation

Full aseptic precautions must be taken and the skin should be prepped and draped. A standard antiseptic solution such as a chlorhexidine-based one should be used to prepare the skin from ankle to groin. Special precautions should be taken when dealing with the skin around the foot as the bacterial load is high and the risk of cross contamination of the operative site greater (Bert et al 2007).

2. Tourniquet

A tourniquet may be used to produce a bloodless field during the procedure although some surgeons may prefer not to. It may be sensible to apply the tourniquet before the operation, reserving inflation for cases where unexpected bleeding has occurred and sufficient visibility cannot be maintained. Tourniquet pressure is determined by the anaesthetist based on the patient's blood pressure; a pressure of 300 mm Hg has been shown to be safe in the lower limb (Wu and Richmond 2003). Using a wide and padded tourniquet minimises the incidence of complications such as compression neurapraxia and temporary paresis (Dandy 1986, Wakai et al 2001, Oragui et al in press).

3. Equipment Setup

In the operating room careful planning and communication is essential in setting up the operating room to allow the anaesthetist to provide a safe anaesthetic and the surgeon to make best use of all the necessary equipment. Special consideration should be placed upon the position of video equipment, the arthroscope, light source, shaving and cauterising systems, the irrigation pump, and an array of arthroscopic hand instruments.

4. Patient Positioning

The patient is positioned supine on the operating table. The operative limb may be placed in a leg holder, so that the joint can be adequately manipulated and opened. If a leg holder is used it should be well-padded and placed high on the thigh and snug. Some surgeons prefer to use a lateral side post and choose to leave the limb on the table, adjusting the patient's knee during the procedure. A lateral side post should be carefully set up to ensure that it will be at the correct level. Incorrect use of the leg holder or unpadded leg holders will increase the risk of pressure injury (Buckenmaier 2002, Malik et al 2009). Adequate light source is essential for placement of the portals (Marx 2000).

ARTHROSCOPIC PORTALS

Accurate placement of portals is essential to optimise visualisation and manipulation of the joint. Palpating and drawing bony landmarks, joint lines and soft tissue structures can help to identify correct sites of entry. The inflow cannula is usually inserted into the supero-medial supra-patella pouch once landmarks have been marked out. The irrigation fluid bag should be raised 1.5 metres higher than the patient and the fluid outflow regulated to ensure distension of the knee joint. This will remove soft tissue such as the synovium and fat pad from view (Aiello 1986). Most procedures require only two portals, however a third portal may be needed for fluid flow with certain irrigation systems.

1. Antero-Lateral Portal

The antero-lateral portal is most commonly employed for diagnostic arthroscopy as it offers superior visualisation of most parts of the knee joint. A 4 mm incision is made approximately 1 cm lateral to the border of the patellar tendon and about 1 cm above the lateral joint line (Aiello 1986). To avoid damaging the meniscus, the cutting edge of the blade should be pointing up when extended through the capsule and synovium, and the scalpel should not plunge too deep as to damage the articular cartilage. A blunt trocar in an arthroscope sheath is then introduced through the portal, directed toward the medial wall of the intercondylar notch, with the knee in approximately 30 degrees of flexion. The arthroscope is then inserted into the sheath, replacing the blunt trocar (Katz & Gomoll 2007, Aiello 1986).

2. Antero-Medial Portal

The antero-medial portal is used for additional visualisation of the lateral compartment, and instrumentation of the medial or lateral compartment structures. It is created with the knee in 30 degrees of flexion, where the soft spot is palpated, 1 cm medial to the border of the patellar tendon and about 1 cm above the medial joint line (Aiello 1986).

3. Postero-Medial Portal

The postero-medial portal is placed in a small triangular soft spot about 1 cm posterior to the postero-medial edge of the femoral condyle, and about 1 cm above the postero-medial joint line. For best results with creating this portal, the knee should be fully distended, with 90 degrees of flexion, external rotation, and abduction. With the arthroscope angled at 30 degrees, it should be possible to view and inspect all the structures in the postero-medial compartment including the PCL, posterior horn of the medial meniscus, and the postero-medial aspect of the femoral condyle and synovial lining (Katz & Gomoll 2007, Buckenmaier 2002).

4. Supero-Lateral Portal

The supero-lateral portal is the best approach for viewing the articulation between the patella and femur diagnostically, with a 70 degree arthroscope. The surgeon should be able to track the patella and assess congruity. The portal should be established as close to the lateral margin of the quadriceps tendon as possible, and about 2.5 cm superior to the supero-lateral edge of the patella (Katx & Gomoll 2007, Aiello 1986).

5. Additional Portals

Other portals exist, and their placement depends on the pathology that is expected or encountered. These include postero-lateral, medial and lateral proximal mid-patellar, and the central trans-patellar tendon portals (Buckenmaier 2002, Aiello 1986).

SOME COMMON ARTHROSCOPIC PROCEDURES

1. Diagnostic Arthroscopy

The most common use for knee arthroscopy has been that of a diagnostic tool and includes staging osteoarthritic degenerative disease, assessing osteochondritis dessicans defects, obtaining biopsies for diagnosis confirmation e.g. rheumatoid arthritis, managing septic arthritis and haemoarthrosis, and assessing tibial plateau fractures. The method should be conducted in the same sequence each time, dividing the knee into individual compartments (suprapatellar pouch and patellofemoral joint; medial gutter; medial compartment; intercondylar notch; posteromedial compartment; lateral compartment; and lateral gutter). This allows for a thorough evaluation and diagnosis of knee joint pathology with the option of intervention if required.

In the current economic climate, the role of diagnostic knee arthroscopy is under review. Although arthroscopy remains the gold standard for the investigation of intra-articular abnormalities, MRI provides a less invasive and more cost-effective alternative (Vincken et al 2007). It is a highly accurate modality for diagnosing meniscal and ACL lesions, although for PCL lesions the sensitivity and accuracy is low (Crawford et al 2007). Its high specificity and negative predictive value confirm its use as the most accurate screening tool prior to therapeutic arthroscopy. In the non-acute setting, when used in combination with a full history and clinical examination, MRI can obviate the need for arthroscopy, saving costs and preventing unnecessary risk.

2. Meniscal lesions

Meniscal injury is the most common indication for the therapeutic application of knee arthroscopy. Meniscal tears are classified intra-operatively according to macroscopic appearance. They may be classified as longitudinal, horizontal, oblique and radial tears, as

well as flap, basket handle, complex and degenerative tears (Aiello 1986). When the meniscus is torn the site will determine whether the lesion is amenable to healing and whether arthroscopic surgery is required to either repair or to excise a portion of the meniscus (Koval & Zuckerman 2004). Excisions can be performed with a basket-punch or a motorised shaver, although the use of radiofrequency ablation has also been demonstrated. It is always preferable to save as much of the meniscus as possible by performing a partial meniscectomy, where only loose fragments are excised (Marx 2000, Pasa & Visna 2005).

3. Loose Body Extraction

Removing loose bodies from the knee arthroscopically is a relatively common procedure and surgeons should select the correct portal depending on the site of the lesion (Gold et al 1995). Due to gravity, intra-articular loose bodies are often found in the posterior compartment and an appropriate portal should be selected (Dandy & O'Carroll 1982). The loose body should then be immobilised, grasped and removed. The smallest should be removed first and then the knee re-examined before closure.

4. Focal Articular Cartilage Lesions

A number of options for the repair or replacement of focal cartilaginous lesions have been used arthroscopically including abrasive chondroplasty, subchondral drilling, microfracture, cartilage transplantation and Autologous Chondrocyte Implantation (ACI) (Spahn et al 2008, Jaiswal et al 2010, 2011). A promising new approach is the use of tissue engineering applications for the arthroscopic replacement of articular cartilage defects using stem cells (Khan et al 2010, Ong et al 2013).

5. ACL Reconstruction

Ligament reconstruction of both the ACL and PCL can be achieved using arthroscopic techniques. A minimally invasive, arthroscopic approach has several advantages: smaller incisions, fewer adhesions, less disruption to the extensor mechanism, less pain, faster rehabilitation and enhanced visualisation of the ligament insertion points. Graft selection is surgeon and patient-dependent and options include autograft (patellar tendon or hamstrings) or allograft (patellar tendon or Achilles' tendon).

6. Osteoarthritis

Techniques such as joint lavage and debridement, loose body extraction, partial synovectomy, and meniscectomy are currently being utilised for treatment of osteoarthritis of the knee (Khan & Hardingham 2010). Arthroscopy may not be beneficial to all patients with

knee osteoarthritis and controversy exists as to whether it provides any additional benefit over conventional treatment (Siparsky et al 2007, Minocha & Khan 2014).

During arthroscopy the severity of osteoarthritis can be graded using the Outerbridge scale grading system. This may help determine the specific arthroscopic technique to be used when treating osteoarthritis. Grade I refers to softening of articular cartilage; grades II and III refer to fragmentation of an area of articular cartilage less than 1 cm and greater than 1 cm respectively; in grade IV there is erosion of articular cartilage through to the underlying bone (Nutton 2009).

DRESSINGS AND POST-OPERATIVE CARE

Once the case is finished, excess irrigation fluid is removed and long acting local anaesthetic may be injected into the joint to help reduce post-operative pain. The wound may be closed with appropriate sutures or steri-strips. Before a compressive wrap is applied, the wound should ideally be covered with absorbable pads and sterile dressing (Buckenmaier 2002, Stuart & Lubowitz 2006). The regime will vary depending on the surgeon's preference and local practice.

Specific post-operative rehabilitation will depend upon findings and procedures undertaken. For basic arthroscopy the patient should be instructed in the use of crutches and exercises, and should continue to use crutches for one to three days. Early exercise is usually allowed however the weight bearing status varies with the procedure performed. Patients may remove dressings for simple arthroscopy after forty-eight hours and maintain hygienic wound care (Buckenmaier 2002, Stuart & Lubowitz 2006). The patient may have a brace applied for up to six weeks if they have undergone a focal cartilage repair procedure (Burkhart 2003).

COMPLICATIONS

Although knee arthroscopy is a relatively safe procedure, complications can and do occur and may depend upon the exact procedure being carried out. Intra-operative complications such as nerve compression injury may result from leg holders or prolonged tourniquet use (Khan et al 2007). Other operative complications include compartment syndrome and vascular injury (Kim et al 2002). Penetrating injuries to the popliteal artery have also been reported (Law et al 2009).

Post-operative complications include pain, haemarthrosis, complex regional pain syndrome, synovial fistula, infection and thrombo-embolism. Most arthroscopic procedures are of short duration and early post-operative mobilisation reduces the risk of thrombo-embolism. For this reason thrombo-prophylaxis is not routinely given in arthroscopic surgery. However, thrombo-prophylaxis is indicated for high risk patients such as those with a previous history of thrombo-embolic disease, morbidly obese patients and procedures that have involved prolonged tourniquet use (Ramos et al 2007).

CONCLUSION

The advantages of arthroscopic surgery are clear when compared to traditional open surgery. Patients recover faster and can quickly resume their normal daily activities. Procedures can be done on a day case basis, and in general are more readily accepted by patients than an in-patient arthrotomy, thus facilitating earlier intervention. Day surgery is also more economical as patients spend less time in hospital and return to work sooner.

In the current economic climate, the role of diagnostic knee arthroscopy is under review. Although arthroscopy remains the gold standard for the investigation of intra-articular abnormalities with the potential benefit of intervention, MRI provides a less invasive, highly accurate and more cost-effective alternative and has a role as a screening tool prior to therapeutic arthroscopy. In the non-acute setting, when used in combination with a full history and clinical examination, MRI can obviate the need for arthroscopy, saving costs and preventing unnecessary risk.

Knee arthroscopy is indicated in the diagnosis and treatment of a variety of knee pathology. A thorough understanding of the principles and techniques of knee arthroscopy and evidence-base is crucial to a successful outcome and low complication rate.

Chapter 387

THE ROLE OF NAVIGATION IN TOTAL KNEE REPLACEMENT SURGERY

James Min-Leong Wong, Wasim S. Khan
and Joyti Saksena*

Department of Trauma and Orthopaedics, Chase Farm Hospital,
Royal Free Hospitals NHS Trust, Enfield, Middlesex, UK

ABSTRACT

Since the introduction of modern implants in the 1970's, Total Knee Replacement surgery has been a great clinical and commercial success. Implants and techniques have continued to evolve, driven by the desire for improved function and longevity. However, inaccurate insertion of these implants may cause them to loosen and fail. Computer navigation has been introduced as a modification to existing surgical techniques to improve the accuracy with which the bones are cut prior to inserting the knee replacement implants. Research continues to see if this potentially costly and time consuming technique can contribute to improved longevity of knee replacements.

Keywords: total knee replacement; navigation; implants; accuracy; longevity; computer

INTRODUCTION

This chapter deals with the role of navigation in Total Knee Arthroplasty, or Replacement (TKR) surgery (Wong et al 2012). Over the past 20 years TKR surgery has enjoyed great clinical and commercial success. Modern implants have been shown to have excellent long term results (Berger 2001, Rodriguez 2001, Laskin 2001) with a high level of patient satisfaction (Ethgen 2004, Noble 2006, Bourne 2010). The most recent published National Joint Registry figures show almost 80,000 TKR's were performed in the UK alone in 2009/10

* Corresponding Author's Email: wasimkhan@doctors.org.uk.

(NJR 2010). This figure is expected to rise, with some estimates projecting a 673% increase from 2005 levels by the year 2030 (Kurtz 2007).

Although better implant designs, materials and patient education has improved the longevity of implants, some knee replacements, due to a combination of surgical, patient and implant factors, do fail. The most common cause for a TKR requiring revision is infection, followed by aseptic loosening and wear (Hossain 2010). Although some of these causative factors for failure are out of the surgeon's control, malpositioning of implants, which can lead to aseptic loosening and early failure (Lotke 1977, Tew 1985, Ritter 1994), is. The final position of the tibial and femoral components of a knee replacement are strongly influenced by the cuts the surgeon makes in these bones, resecting the arthritic articular surfaces and preparing them to accept the knee prosthesis. The accuracy of these cuts will affect the ultimate alignment and stability of the prosthetic joint, in addition to soft tissue and ligament balancing.

Computer assisted surgery, or navigation, has been developed to improve the accuracy of these cuts. An increasing number of navigation options are now commercially available, usually designed by implant manufacturers to be used solely with a specific knee implant system. Despite ongoing advances, the use of these systems has thus far been limited as they are cumbersome and time consuming to use, as well as costly.

The vast majority of TKR implants in use today are versions of the "condylar" knee replacements developed in the 1970's. The introduction of this design resulted in not only a marked improvement in results and longevity, but also reproducibility. Jigs and guides were introduced to enable the surgeon to reliably determine the orientation and alignment of the tibia and femur, and use this to guide his subsequent bony cuts. Most knee systems utilise a combination of intramedullary and extramedullary instrumentation, together with extensive visual referencing, to guide appropriate resection of bone.

Figure 1. A modern knee replacement prosthesis. (Picture reproduced courtesy of Zimmer Inc., Warsaw, Indiana USA).

Condylar knee replacements incorporate an anatomically shaped femoral component, with an anterior flange to articulate with the patella. The cobalt chrome femoral component articulates with a polyethylene tibial insert, which is usually attached to a titanium tibial component (Fig 1). Inserting these implants involves resection of the bone ends to create parallel and equal spaces in flexion and extension, and then balancing the soft tissues to convey stability.

These implants are usually cemented in place using acrylic polymethylmethacrylate cement, but can be coated in materials which enable an uncemented, biological fixation.

The majority of surgeons are guided in cutting the femur with the aid of intramedullary guide. A rod is inserted up the femoral canal, thus defining its anatomical axis. A cutting jig is then applied to this rod, enabling the distal femur to be cut in at the desired angle relative to the anatomical axis of the femur.

Figure 2. Intramedullary femoral instrumentation. A drill is passed up the intramedullary femoral canal, approximating the anatomical axis. Cutting the distal femur is guided by a rod passed up the drill hole and a cutting jig set to resect bone. This is usually set at 5-7 degrees from the estimated anatomical axis (Images courtesy of Zimmer Inc. Warsaw, Indiana).

Cutting guides are then applied to allow further bone cuts to be made to accommodate the anatomically shaped femoral component, with the majority of surgeon's using a guide which enables them to place these cuts in 3 degrees of external rotation relative to the posterior femoral condyles.

Figure 3. Further femoral instrumentation determine the size and rotation of the femoral component and then guide further bone cuts (Images courtesy of Zimmer Inc. Warsaw, Indiana).

When cutting the tibial component, many surgeons use extramedullary instrumentation, placing an alignment guide parallel to the tibia, and cutting the tibia in a plane perpendicular to this.

Once these cuts have been made to the surgeon's satisfaction, the gap between the cut femoral and tibial surfaces is checked to ensure a symmetrical gap in flexion and extension. If the gap is found to be asymmetrical, it is corrected by a combination of soft tissue releases or further bony cuts. Only after the soft tissues have been appropriately balanced are the implants inserted and secured in place.

Figure 4. Extramedullary tibial instrumentation. This guide is placed on the anterior surface of the tibia. The mechanical axis is estimated by placing this guide over anatomical landmarks and a cutting jig is then applied to guide bone cuts perpendicular to this (Images courtesy of Zimmer Inc. Warsaw, Indiana).

The Need for Navigation

The conventional instrumentation described above is largely similar amongst manufacturers and has not changed significantly over the past 20 years. Even in experienced hands, using conventional instrumentation to guide bone resection can still result in component malposition. It is estimated that up to 10% of total knee replacements have significant (> 3 degrees) errors in mechanical alignment (Stulberg 2002). Mechanical axis malalignment has been proven to adversely affect implant function and survival (Jeffery 1991, Ritter 1994, Wasielewski 1994), particularly if the erroneous bony cuts result in a significant varus deformity (Jeffery).

Figure 5. Preoperative long leg and lateral xrays of a patient previously affected by rickets and previous bilateral total hip replacements. The bowed femurs and hip replacements make femoral intramedullary instrumentation difficult.

Furthermore, the use of conventional instrumentation to accurately resect bone can be technically very difficult in the presence of abnormal patient anatomy, poor exposure and preoperative bone loss. There are occasions when using intramedullary instrumentation is not possible at all. For example patients with previous trauma and residual bony deformity, or with pre-existing metal implants such as a total hip replacement, which may prevent the use of an intramedullary guide.

At a time when TKR's are now being performed in ever younger and more demanding patients, there is a need to improve the accuracy of existing surgical techniques, in the hope this will maximise the longevity and function of these implants. Computer assisted, or navigated, surgery is a technique previously well known in neurosurgery to guide precise surgery. It has now been adapted to aid the accurate implantation of total knee replacements.

Navigation Systems

Various types of navigated surgical systems are now available. Most are produced by manufacturers of total knee replacement implant systems and are generally recommended to be used with specific TKR implants. All these systems develop a three dimensional model of

the patient’s knee and maps the position of the surgeon’s instruments in relation to this model. This can then be used to guide the surgeon to make accurate bony cuts.

Image-guided navigated systems utilise data obtained preoperatively or intraoperatively to build a three dimensional model of the knee which is then used to guide bony cuts. Most of these systems utilise preoperative imaging, usually in the form of CT scans, but some also use intraoperative fluoroscopy to map anatomical landmarks.

(A)

(B)

(C)

Figure 6. (Continued).

(D)

(E)

Figure 6. A. An example of an imageless navigation system. Reflective markers are drilled into the femur and tibia (3), and their location is detected by an infrared (2) camera attached to a computer (1). B,C. A stylus with another reflective marker attached is then used to register multiple anatomical landmarks to enable the computer to develop a three-dimensional model of the knee D. Cutting guides with a further reflective marker attached are then placed on the knee. E. The monitor display is used to guide the positioning, angulation and rotation of the cutting guide to ensure that the bone is accurately cut. (Images courtesy of B Braun Inc, Tuttlingen, Germany).

Once the computer has developed a three dimensional model of the patient's lower limb, bone cuts can then be accurately planned. Navigation systems can then use this information intraoperatively. The position of the patient's knee is registered into the navigation system, which then correlates this with the three dimensional model. The most common means of doing this is the use of reflective markers which are drilled into the femur and tibia, and a further marker which can be placed on surgical instruments and cutting jigs. Infrared cameras which are coupled to an emitter and the navigation computer can track the movements of the markers drilled into bone and marked surgical instruments relative to each other. The computer can thus guide the surgeon to ensure that the cutting jigs are deployed in exactly the correct position.

A variation of this approach is an imageless navigation system. This is also called morphing surface navigation and utilizes a large database of knee CT scans. Once the markers have been drilled into the femur and tibia, a marked stylus is used to register multiple

anatomical landmarks (figure 6). The computer system then uses the information on its database to build or morph a three dimensional model of the patient’s knee which fits the registered anatomical landmarks.

Figure 7. A three-dimensional model of the knee has been produced based on a patient’s CT scan, allowing the desired cuts to be planned by the surgeon prior to surgery. (Image courtesy of Depuy Orthopaedics Inc., Warsaw, Indiana).

It should be recognised that all of these systems increase the operative time required to perform a knee replacement (Weng 2009). Furthermore, in the current health economy the cost of installing and maintaining these systems may prove prohibitive, with one author estimating the cost of purchasing the computer system and software approaches \$150,000, with a further \$20,000 a year spent on maintenance. These factors have limited the use of navigated systems, particularly at a time when the need for increased efficiencies and cost reduction in operating theatres is being stressed.

Customised Patient Instrumentation

The next evolution of navigated knee surgery is the manufacture of instrumentation or cutting guides to specifically fit an individual patient. These systems involve building a model of the knee based on preoperative CT or MRI scans and taking images of the hip and ankle to determine mechanical alignment. The ideal cuts are planned by the surgeon based on this model (Figure 7) and then custom designed cutting blocks are manufactured using three-dimensional printing techniques to fit that individual patient's knee and produce the planned cuts. Some of these systems produce patient specific cutting guides that fit directly onto a patient without the need for any conventional instrumentation, others guide the placement of pins into the bone, and conventional cutting blocks are then passed over these pins (Figure 8).

Figure 8. Customised patient specific instruments are manufactured to fit over the patient's bone and guide a saw blade to accurately.

This strategy has the advantage of being a faster procedure, with reduced tourniquet times when compared with conventional knee replacement surgery (Hafez 2006). There is no need to drill markers into the tibia and femur, as the time consuming anatomical landmark registration is no longer necessary and, unlike conventional knee replacements, no intra- or extra-medullary guides are required. All patients will however, need to undergo a preoperative CT or MRI, and this, combined with the need to manufacture cutting guides for each procedure, does mean that there is a lead time for each surgery and an added cost.

RESULTS

Multiple prospective randomised controlled trials have now been performed comparing various navigated systems with conventional total knee replacements. Many have shown significant improvements in coronal alignment (Mullaji 2007, Dutton 2008), with better restoration of the mechanical axis of the limb on post operative radiographs. CT scans have

also been used to assess postoperative implant position showing improved accuracy in the coronal (Mizu-uchi 2008, Hernandez-Vacquero 2010) and sagittal planes (Chauhan 2004, Matziolis 2007).

Two of these trials also showed significantly improved rotational alignment of implanted prostheses (Chauhan 2004, Mizu-uchi 2008). Other trials, however, have showed no difference in alignment and rotation (Kim 2007, Lutzner 2008), although one of these did show a reduction in large deviations of mechanical axis in the navigated group. It should be noted that errors in alignment have not been completely eradicated by navigation, and errors in inserting and cementing implants in place has been shown to cause malpositioning despite perfect bony cuts (Catani 2008)

Studies have also investigated the potential improved accuracy of navigation in the presence of significant deformity.

When used in the presence of significant femoral bowing in a Taiwanese population, navigated TKR's were found to be significantly better at reproducing a normal mechanical axis than conventional TKR (Huang 2011). A further study also showed improved leg alignment when performing navigated TKR's in the presence of large frontal plane deformities (Hernandez-Vacquero 2010).

With an increasing number of trials available, two META-analyses have now been published, with mixed results. Whilst one has shown significantly improved alignment and rotational orientation when compared to conventional TKR (Mason 2007), another showed no overall difference in alignment, but a decrease in critical deviations from the mechanical axis in excess of 3 degrees (Bauwens 2007).

Whether these improvements in accuracy will translate to improved function and implant survival, however, remains to be seen. A functional analysis of patients at two years post surgery has shown no difference in clinical outcome between navigated and conventional TKR's (Spencer 2007). As yet, no studies have been able to demonstrate a survival benefit for Navigated TKR's.

A further study has investigated whether the added cost of navigation (an estimated \$1500 per operation) is justified (Novak 2007). The argument was made that the improved alignment will reduce the need for a potentially very costly early revision procedure, and this study concluded that navigated surgery was a cost-saving and cost-effective modification to conventional total knee replacement.

CONCLUSION

Whilst excellent results continue to be reported for the vast majority of total knee replacement implants, even the best implants can fail due to malpositioning. Using conventional instrumentation, significant errors in position can occur in up to 10% of patients. Navigated knee replacement systems have been devised to reduce the amount of error in implant positioning.

Despite advances in navigation technology, however, many surgeons still find these systems cumbersome and time-consuming to use. They are, of course, also expensive to acquire and may require additional CT or MRI scans. As a result, navigated knee replacement systems have not entered widespread use.

Customised patient instrumentation may achieve more widespread acceptance, although these systems are still in their infancy and long term results are yet to be published.

It should also be remembered that TKR is not just a procedure on bony abnormality, but also a procedure to correct soft tissue imbalances. Despite many studies showing improved alignment none have as yet shown a functional improvement or improved implant survival.

As navigation continues to improve, its role in future knee replacement will become clearer. Whether this role is its involvement in all total knee replacements, or limited to difficult patients with distorted anatomy, is dependent on future clinical results, improvements to navigated systems and of course the long term health economy.

ABSTRACT

Ovarian cancer is the second most common gynecologic malignancy among women worldwide after endometrial cancer and the most common cause of death in women with gynecologic malignancies. Because of the increasing life expectancy experienced worldwide it is estimated that the incidence of this aggressive disease will significantly increase in the next few decades. Among all cases diagnosed with ovarian cancer the histopathological subtype consisting of epithelial tumors represents the largest part and has been widely studied. However, there is still an important number of patients who are diagnosed in an advanced stage of the disease, when disseminated bulky tumors are already present. It has been demonstrated that the most frequent patterns of spread are represented by the peritoneal, hematogenous and lymphatic route, all of them being responsible in different proportions for the presence of upper abdominal burden which sometimes is present from the moment of initial diagnosis. In all these cases the therapeutic mainstay remains cytoreductive surgery, followed by taxanes and platinum based adjuvant chemotherapy. When it comes to long term outcomes, among various prognostic factors such as age, stage at diagnosis, histopathological subtype, differentiation grade and residual disease, only residual disease has been widely demonstrated to strongly impact survival; at the same time, the amount of residual tumor burden at the end of debulking surgery is the only parameter which is influenced by the treating physician's experience. The presence of upper abdominal disseminations has been considered for a long period of time to be the sign of a tumor with a more aggressive biology and was considered as a poor prognostic factor. The main invaded organs in the upper abdomen consist of liver and porta hepatis, diaphragm, and less

common, the spleen. While in cases presenting hepatic involvement the presence of hematogenous disease has been accepted as a poor prognosis factor and was classified the disease as FIGO stage IV, there was no explicit specification whether parenchymatous splenic involvement should be classified as part of the same FIGO stage. Initially a poorer outcome was reported for patients submitted to splenectomy as part of debulking surgery for advanced stage epithelial ovarian cancer, this fact being related to a more aggressive biological behaviour of the tumor. Other studies have stipulated the fact that the presence of splenic metastases is an independent poor prognosis factor but they could not distinguish whether the poorer outcome is related to the presence of hematogenous involvement of the upper abdominal parenchymatous viscera or to the co-existence of bulky left quadrant upper abdominal tumoral burden.

However, the initial results were strongly influenced by the small number of cases included and by the different characteristics of the included patients. For example patients submitted to splenectomy as part of primary and secondary cytoreduction were included in the same study so the results were also influenced by the moment of performing the surgery.

More recently, a significant difference in terms of survival was reported for hematogenous versus peritoneal splenic metastases and concluded that their presence should be considered as an explicit criterion for FIGO stage IV disease. Although it is a safe and effective surgical procedure, performing a splenectomy as part of cytoreductive surgery for advanced stage or relapsed ovarian cancer might associate a higher rate of postoperative morbidity rather due to the fact that in these cases ovarian cancer becomes a systemic disease with multiple visceral involvements, imposing multiple visceral resections in order to achieve an R0 resection; in all these cases the postoperative outcomes are influenced by a cumulative postoperative risk related to each performed resection in part.

However, since splenectomy can be safely performed with acceptable rates of postoperative complications it should be routinely performed in cases presenting splenic tumoral involvement in order to increase the rate of complete cytoreduction. This chapter focuses on the patterns of spread, prognostic factors of patients with splenic involvement, safety and effectiveness of splenectomy as part of cytoreductive surgery for advanced stage and relapsed epithelial ovarian cancer.

INTRODUCTION

Splenic tumors usually develop in the context of lymphoreticular malignancies, while most commonly splenic involvement from solid tumors occurs in breast, lung, melanoma, colorectal, gastric and ovarian cancer [1, 2, 3]. In the majority of cases splenic metastases from solid tumors occur in the context of disseminated hematogenous spread and are associated with other visceral tumoral lesions [1]. The prevalence of splenic metastases from solid tumors is mainly obtained from large autopsy studies and range between 2.3-7.4%, the largest investigated series being conducted by Berge who reported 312 splenic metastases among 7165 autopsies for cancer [1]. In the last decades large studies on living patients have been conducted and reported that the splenic tumoral involvement (determined by histopathological studies of the splenectomy specimen) occurs in 1.1-1.3% of cases while the incidence of splenic metastases at preoperative imagistic studies is up to 0.15% (in a Japanese study conducted on 24761 patients 37 cases were diagnosed ultrasonographically with splenic involvement) [4, 5]. The rarity of splenic tumoral involvement is explained through multiple mechanisms: inhibitory influence of the splenic microenvironment on neoplastic cells, the

sharp angle and tortuosity of the splenic artery which associates a modified blood flow through the splenic vasculature, the lack of splenic lymphatic afferents, the rhythmic contractility and the role of barrier of the splenic capsule [2, 3, 6-8].

When it comes to splenic involvement in advanced stage ovarian cancer, three patterns of spread have been advocated: hematogenous, peritoneal and lymphatic way. However, tumor cell metastasis involves multiple mechanisms including disconnection of the tumor cell from the solid tumor, invasion of the malignant cells into the blood, lymphatic flow or ascites, escape from the immunological filters, adhesion to endothelial cells, extravasation from the blood or lymphatic flow and angiogenesis induction [9].

PATHWAYS OF SPLENIC INVOLVEMENT

Ovarian cancer metastasizes more likely via intraperitoneal dissemination followed by the hematogenous and lymphatic route. Intraperitoneal spread is influenced by growth factors and cytokines which will induce the epithelial – mesenchymal transition, responsible for the increased motility and invasion ability of the tumoral cells [9]. This transition consists of dramatic phenotypic changes which will provide epithelial to mesenchymal cell conversion. Once malignant cells acquire mesenchymal properties, they will express a higher capacity of adhesion and an increased motility leading to a higher capacity of inducing distant metastases [9]. Recently the epithelial-mesenchymal transition was classified into three distinct categories, only type 3 of transition being considered as part of tumor progression; the other two types are considered to be part of embryogenesis (type 1) and inflammation and tissue damage repair respectively (type 2) [10]. Once a type 3 epithelial-mesenchymal transition occurs, distant metastases are expected. After evading from the ovarian capsule, the malignant cells will become part of the peritoneal fluid and will follow its' normal route into the peritoneal cavity [11]. In the study conducted by Carmingani et al. it has been demonstrated that the malignant cells will be transported by the peritoneal fluid according to physical forces such as intraperitoneal fluid hydrodynamics and gravity; according to this study, preferential tumor seeding will develop in the pelvic space, near the ileocecal valve, along the right paracolic gutter, diaphragm and greater omentum. The diaphragmatic and omental involvement were explained by the presence at this level of lymphatic lacunae on the diaphragmatic peritoneal surface and lymphoid tissue of the greater omentum respectively [12]. In contrast, if the intraperitoneal fluid is reduced, malignant cells are restricted in motion and will implant nearby the primary tumor leading to rectal or urinary bladder invasion [13]. Although it is not a common site of involvement, the spleen can be interested by the development of isolated peritoneal nodules or by contiguity from the greater omentum. In the latter situation involvement occurs by contiguous spread to the attached colon, spleen, gastroc-colic ligament, stomach and even pancreas and necessitates performing of extended left upper quadrant resections in order to provide a local control of the disease [14].

Another pattern of spread is the lymphatic route; however it has been demonstrated that this pathway is rather a secondary route which develops later in the evolution of the disease leading to pelvic and para-aortic lymph node metastases. When it comes to the upper abdomen lymphatic involvement, Feki et al. demonstrated that once the malignant cells disseminate into the greater omentum and diaphragmatic peritoneum, they will migrate

through the milky spots which are mainly found at these levels, pass through the mesothelial barrier and get into the lymphatic flow. The authors also hypothesized that ovarian malignant cells migrate primarily via lymphatics and block the lymphatic clearance of the peritoneum [11]. However the presence of distant lymphatic metastases has been considered as a poor prognostic factor and cases diagnosed with lymph node metastases have been classified as FIGO stage IIIC [15].

As for the hematogenous route of dissemination, although it is less frequently seen, it is associated with the poorest prognostic. Hematogenous route is incriminated whenever parenchymal organ involvement is encountered and has been widely studied in patients with ovarian cancer liver metastases. Hematogenous liver metastases are usually associated with decreased survival even if the principles of radical surgery are applied; these findings enabled the International Federation of Gynecology and Obstetrics to classify these cases as stage IV disease status [16, 17]. When it comes to splenic hematogenous involvement, initially there was no explicit mention whether these patients should be classified as FIGO stage IV, especially due to the low number of cases diagnosed with parenchymatous splenic involvement [18], the reported incidence of splenic metastases at the time of primary cytoreduction ranging between 0 and 41% [19-22]. However, FIGO classification presented in 2014 clearly distinguished between parenchymatous and peritoneal seeding and classified capsular splenic lesions as stage IIIC of the disease while the parenchymatous lesions were classified as FIGO stage IV.

Splenectomy as Part of Debulking Surgery in Advanced Stage Ovarian Cancer with Bulky Upper Abdominal Involvement

It has been widely demonstrated that the best therapeutic option to achieve an increased long term survival in advanced stage ovarian cancer is obtaining a complete cytoreduction with no residual disease. In Bristow's meta-analysis involving 6885 patients diagnosed with advanced stage ovarian cancer each 10% increase in the proportion of patients undergoing maximal cytoreduction was associated with a concomitant 5.5% increase in median cohort survival time [23]. The same study reported that the percentage of patients submitted to optimal cytoreduction widely varies in the literature reported data from 15% to 85%; these differences are mostly related to the presence of extended upper abdominal disease at the time of diagnosis [23]. According to the study conducted by Eisenkop in 2001, the disease sites which are usually associated with incomplete cytoreduction are the diaphragm (in 76.3% of cases), portal triad (in 77.1% of cases), mesentery (in up to 82% of cases) and omentum, spleen and pancreas (in 13% of cases) [24]. The authors included in their study 393 physicians and questioned them regarding the therapeutic strategy and the number of performed procedures in order to achieve complete cytoreduction; in the meantime the responders were asked to define the notion of optimal cytoreduction. A median of 95% of patients were reported to be submitted directly to cytoreductive surgery while in the other 5% of cases neoadjuvant chemotherapy followed by surgery was the treatment of choice. At the question regarding the number of performed procedures as part of debulking surgery, a median value of nine procedures (range 0-15) was reported. When it comes to the definition of optimal cytoreduction, 12% of the responders defined it as no residual disease, 13.7% used a 5 mm threshold, and 60.8% used a 1 cm threshold while 12.6% used a 1.5 – 2 cm threshold.

When questioned about the possibility of performing upper abdominal resections in order to maximize the cytoreductive effort, 60.1% of respondents declared that they excise the omentum en bloc with splenectomy and distal pancreatectomy if necessary, 16.2% do not perform this type of surgery due to the lack of experience and 23.7% do not perform it due to an unacceptable risk of postoperative complications or due to the lack of data establishing the efficacy of the procedure. In the meantime 83.9% of the respondents favoured the development of post-fellowship training in debulking surgery. Those who voted against post-fellowship training also invoked concerns related to the efficacy of multiple resections ($p = 0.01$) [24].

However, due to the improvement achieved in surgical techniques regarding the upper abdominal resections and in the postoperative management of the patients submitted to extended hepato-bilio-pancreatic surgery, these type of surgical procedures were successfully implemented in the armamentarium of the oncologic surgeon. It has been widely demonstrated that addition of upper abdominal resection provides a significant increase of the rate of complete resection to no residual disease cytoreduction with acceptable rates of postoperative morbidity, so radical surgery in the upper abdomen is widely performed nowadays [25-28].

In the study conducted by Oliver Zivanovic between 1989 and 2005, 490 patients submitted to surgery for FIGO stage IIIC ovarian cancer at Memorial Sloan Kettering Center were introduced [29]. The patients were classified according to the presence of upper abdominal disease in three groups: group 1 – no upper abdominal disease and included 116 cases, group 2 – upper abdominal disease < 1 cm and included 161 cases and group 3 – bulky upper abdominal disease and included 197 cases. Optimal cytoreduction was considered whether residual disease was < 1 cm and was achieved in 81%, 63% and 39% of cases in groups 1, 2, and 3 respectively ($p < 0.001$). The patients were also stratified according to the time of surgery: before 2001 and after 2001. The distribution of the upper abdominal involvement was similar for both time periods ($p = 0.289$); however the majority of surgical procedures involving upper abdomen resections were performed after 2001 (66 cases were submitted to upper abdominal resections after 2001 compared to 12 cases submitted to upper abdominal procedures before 2001, $p < 0.001$). The rate of optimal cytoreduction was significantly higher after 2001 (40% before 2001 versus 78% after 2001, $p < 0.001$), this effect being more pronounced in patients with bulky upper abdominal disease (11% before 2001 versus 70% after 2001, $p < 0.001$) [29]. In another study conducted by the same author involving 526 patients with stage IIIC ovarian cancer 158 cases had minimal upper abdominal involvement, 243 cases had bulky abdominal involvement while the other 125 cases had no upper abdominal involvement [30]. The authors demonstrated that the long term outcomes were not influenced by the location of the tumoral burden; the most important predictor for an improved outcome remained the completion of the resectional process: patients submitted to suboptimal cytoreductive surgery reported comparable low median progression free survivals (14 months for cases with no upper abdominal disease, 11 months for cases with minimal upper abdominal disease and 13 months for patients with bulky abdominal disease respectively). Although in cases submitted to complete cytoreduction to no residual disease patients with bulky upper abdominal involvement had a poorer outcome when compared to those with no upper abdomen involvement, the benefits of radical surgery were still present, underlining the necessity to maximize the debulking effort whenever is possible [30].

Initially large studies have been conducted on the issue of upper abdominal surgery in advanced stage ovarian cancer and discussed about the benefits of multiple visceral resections including hepatic, diaphragmatic, splenic, pancreatic and upper abdomen lymph node dissection; it has been demonstrated that all these surgical procedures can be safely performed, with acceptable rates of postoperative complications and in the meantime with increased rates of long term survivors [14, 16, 28].

The necessity to perform splenectomy in order to achieve an R0 resection and the complications related to this surgical procedure widely vary between the existing studies. The largest studies which include splenectomy as part of upper abdominal resections are summarized in Table 1.

These data come to suggest that splenectomy was increasingly associated as part of debulking surgery in the last two decades leading to an increased rate of cytoreduction to no residual disease; in the meantime association of splenectomy does not seem to increase the postoperative complications. For example, in the study conducted by Pierluigi Beneditti Panici regarding the predictors of postoperative morbidity after cytoreduction for advanced stage ovarian cancer 121 patients were included, submitted to 212 surgical procedures [33]. At diagnosis 96 patients were diagnosed with FIGO stage IIIC disease while the other 25 cases had FIGO stage IV disease. Upper abdominal metastatic sites included diaphragmatic involvement in 62 cases, liver involvement in 43 cases, stomach in 16 cases, biliary tract and porta hepatis in 24 cases, spleen in 53 cases and pancreatic tail in 14 cases. The main associated resections were diaphragmatic peritonectomies in 28.9% of cases, diaphragmatic resections in 31.4% of cases, glissonian resections in 15.7% cases, liver resections in 13.2% of cases, partial gastrectomies in 9.9% of cases, distal pancreatectomies in 13.2% of cases and splenectomies in 39.6% of cases. When it comes to the extent of cytoreduction, an R0 resection was achieved in 75.1% of cases, while in other 20.7% of cases a residual disease < 1 cm; in the other 4.1% of cases an R2 resection (defined as residual disease > 1 cm) was performed. At univariate analysis diaphragmatic, pancreatic, gastric and splenic resections were associated to a prolonged hospital in stay while in multivariate analysis only diaphragmatic resections and pancreatic resections were associated with a longer hospitalization. Intraoperative and postoperative complications occurred in 29.7% of cases. Intraoperatively the main complication consisted of severe blood loss and was observed after multiple liver resections for disseminated hepatic lesions while postoperatively the complication rate was influenced by the number of associated resections. In multivariate analysis diaphragmatic resections, diaphragmatic peritonectomies, pancreatectomies and hepatic surgery were associated with an overall increased risk of postoperative complications while diaphragmatic, hepatic, pancreatic and biliary tract resections were independent predictors of severe complications. When studying the risk of developing a pleural effusion it was significantly influenced by performing diaphragmatic surgery, hepatic and pancreatic surgery. Although splenectomy was associated with an increased postoperative hospitalization, splenic resection did not predispose to a higher rate of postoperative complications; moreover, the authors also concluded that the surgical procedure with the most severe postoperative complications remains pancreatic resections [33].

Based on the observation that a significant number of patients present bulky upper abdominal disease at the time of diagnosis and necessitate multivisceral en bloc resections, Hoffman et al. conducted a study on six patients submitted to en bloc resection in the left upper abdominal quadrant [14].

Table 1. Studies in which splenectomy was included as part of upper abdomen debulking surgery

Author	Period of the study	Year of publishing the study	No. of cases	No. of performed splenectomies (%)	R0 definition	R0 resection (%)	Postoperative complications	Splenectomy related complications	30 days postoperative mortality
Cliby et al. [31]	1998-2001	2004	41	7 (17%)	Largest residual tumor <1cm	90%	19.6%	NR	2.4%
Chi et al. [27]	1998-2002	2004	140	9 (6.4%)	Residual tumor <1cm	62.8%	5% (Clavien Dindo grade 3-5 complications)	NR	0.71%
Eisenhauer et al. [16]	1998-2003, splenectomy was performed after May 2000	2006	262	17 (6.4%)	No visible residual disease	19.08%	12%	NR	NR
Hoffman et al. [14]	2002-2004	2007	6	6 (100%)	No residual disease	33%	50%	NR	0
Chi et al. [32]	January 2001- December 2006	2010	141	45 (32%)	No gross residual disease	30%	22%	NR	1.4%
Panici et al. [33]	September 2006- May 2014	2015	121	53 (43.8%)	No visible residual disease	75%	29.7%	NR; however splenectomy was not a predictor of severe complications	0

Starting from the hypothesis that almost all women with advanced stage ovarian cancer already have omentum tumor burden which might spread via the ligaments to the surrounding viscera, the authors proposed an en bloc technique of the involved organs in order to achieve an R0 resection: after an initial phase of exploration of the peritoneal cavity mobilization of the involved colic segment is required in order to determine which is the length of bowel which will be resected and how many anastomoses will be necessary. If the splenic flexure is involved by contiguous spread, it will be not mobilized. Then the gastrocolic ligament is dissected close to the stomach providing a good access in the omental bursa; the anterior surface of the pancreas and the splenic vessel are explored. Bulky left abdominal tumor will be removed en bloc with the spleen, pancreatic tail, splenic flexure and paracolic gastrectomy if the stomach is involved. Postoperative complications were described in three patients and consisted of pulmonary embolism associated with a small anastomotic leak in one case, left quadrant abscess in one case and gastric leak requiring re-operation in the third case. The reported disease free survival ranged between 2-12 months, one patient refusing adjuvant chemotherapy. The authors demonstrated the efficacy of en bloc resection in these cases underlining the advantage of a more complete apparent clearance of the tumor compared to piecemeal resection and secondarily a benefit in terms of survival [14].

However, although surgical technique continued to improve in the last decades, there are still cases in which a complete resection to no residual tumor cannot be reached. In the study conducted by Francesco Raspagliesi, 37 patients with advanced stage ovarian cancer with upper abdominal dissemination were included. In 67% of cases omental bursa was involved, consisting of anterior pancreatic surface, caudate lobe, supra-gastric lesser sac, porta hepatis or celiac trunk involvement [28]. Debulking surgery consisted of omental removal en bloc with the lesser omentum, gastro-colic ligament, surface of the pancreas, caudate lobe, celiac lymph nodes and portal nodes. Other associated procedures consisted of splenectomy in 35% of cases, diaphragmatic resections in 21.6% of cases, large bowel resections in 54% of cases or small bowel resections in 18.9% of patients. Splenic spread was present in 12 of the 25 cases presenting omental bursa involvement. In three cases residual disease < 5 mm was present at the end of debulking surgery due to the presence of deep infiltration of porta hepatis or celiac trunk. No postoperative complication was related to the association of splenic resection. The authors demonstrated the importance of omental bursa exploration at the time of cytoreductive surgery in order to achieve a complete resection and concluded that this region could be the „sanctuary” of residual disease which might be responsible to splenic lymph node tumor spread [28].

In a similar study conducted by A. Martinez involving 28 patients with upper abdominal tumor burden complete cytoreduction to no residual disease was achieved in all but one patient who was cytoreduced to millimetric residual disease. Splenectomy was safely associated in 10 cases; major postoperative complications occurred in 35,7% of cases, none of them being related to the association of splenic resection [34].

Other reported factors associated with an improved outcome after cytoreductive surgery for stage IIIC ovarian malignancies with splenic involvement were the histological grade and the adjuvant chemotherapeutic treatment. In the study conducted by Zheng et al. on 32 patients with epithelial ovarian cancer submitted to splenectomy as part of debulking surgery at Zhejiang Cancer Hospital between 1998 and 2006 the univariate analysis revealed the influence of the histological grade, residual tumor and cycles of chemotherapy on the overall survival ($p < 0.05$) while in multivariate analysis only residual tumor and association of

adjuvant chemotherapy impacted on survival. After a median follow up of 38 months the estimated 2 year and 5 year survival were 70% and 36% enabling the authors to consider that splenectomy can be successfully associated as part of debulking surgery [35].

Splenectomy as Part of Cytoreductive Surgery in Advanced Stage and Relapsed Ovarian Cancer

Once the benefits of extended upper abdominal resections in advanced stage ovarian cancer were widely demonstrated, further studies were conducted on the issue of splenectomy as part of cytoreductive surgery. However, due to the fact that splenic involvement is not such a frequent situation, initially only case reports or case series have been described, leading to conflicting results regarding the benefits and postoperative complications [36-38]. One of the first series reported on this subject was conducted by Paul Matigbay and involved 112 patients submitted to splenic resections during primary and secondary cytoreductive surgery for advanced stage and relapsed ovarian cancer at Mayo Clinic between 1983 and 2003 [39]. At the time of the study 66 patients were submitted to primary cytoreduction while the other 46 cases underwent secondary cytoreduction for recurrent disease. Splenectomy was performed for direct splenic involvement in 46% of cases, while an en-bloc resection to facilitate the removal of peri-splenic disease was performed in 41% of cases; in other 13 per cents splenectomy was imposed by the intraoperative trauma leading to an uncontrollable haemorrhage. Other associated visceral resections consisted in intestinal resections (performed in 52% of cases at the time of primary cytoreduction and in 48% of cases at the time of secondary cytoreduction) and urinary tract resections (performed in 3% of patients at the moment of primary cytoreduction and 7% of patients at the moment of secondary cytoreduction). Intraoperatively the median number of units of packed red blood cells was 2 units while on the whole in stay period the median number of transfused red blood cells was 4. Reoperation due to postoperative bleeding was needed in two cases: one case developed a severe intravascular coagulopathy with diffuse bleeding areas including the splenic bed while in the second case the bleeding originated from the pelvic sidewall. Postoperatively 6,3% of cases developed wound infection, 4,5% developed postoperative pneumonias, 8% experienced thromboembolic events and 4,5% developed a septic status due to fungal infection (in two cases), anastomotic leak (in one case) and of unknown origin (in other two cases). However none of these septic complications could be directly attributed to the splenectomy; the 30-days postoperative mortality rate was 5% and was associated to septic shock due to an anastomotic leak in one case and due to respiratory failure secondary to pneumonia in other two cases. Other causes of early postoperative mortality were thromboembolic events in two cases while in another case the death cause remained unknown. No postoperative pancreatic leakage was reported. When it comes to the long term outcomes, the primary cytoreduction group reported an overall median survival time of 21.6 months with an estimated 2-year survival of 46.2% while the median overall survival and the estimated 2 year survival in the secondary cytoreduction group were 20.3 months and 42.3% respectively. The strongest predictor for long term survival remained the completion of the resection; when it comes to the various patterns of spread, no difference in terms of survival was obtained in parenchymatous versus peritoneal seeding of the spleen. This was the largest reported series regarding the safety of splenectomy as part of debulking surgery for advanced

and relapsed ovarian cancer; however the study failed to identify other prognostic factors and which patients could mostly benefit from splenectomy as part of debulking surgery in advanced stage and recurrent ovarian cancer. This fact could be explained by the heterogeneity of the studied cohort, which included patients at different moments of disease evolution. Moreover, the study also included a number of 15 cases in which splenectomy was necessary for haemostatic purpose due to an intraoperative uncontrollable haemorrhage [39].

In a similar study conducted by Gemignani et al. and published in 1997 the authors included six patients submitted to splenectomy during cytoreductive surgery for isolated parenchymal splenic metastasis [40]. The study retrospectively reviewed data of patients submitted to surgery between 1991 and 1997. The single reported complication was a diaphragmatic tear which necessitated chest tube placement. At a median follow-up of 25.5 months all patients were alive and free of recurrent disease [40].

In order to determine if the presence of splenic metastases is the reflection of a more biologically aggressive disease and if performing a splenic resection could increase survival, Scott Eisenkop et al. conducted a study on 356 patients submitted to complete cytoreduction for stage IIIC ovarian cancer; in 49 cases splenectomy was required in order to maximize the cytoreductive effort while in the other 307 patients an R0 resection was feasible without requiring splenectomy [41]. Patients requiring splenectomy were older ($p = 0.05$), had a poorer general status ($p < 0.001$), a higher volume of ascites ($p < 0.001$) and a larger maximal diameter of metastatic disease ($p = 0.004$); in the meantime cases in which splenectomy was required necessitated more often other extended resections such as pelvic exenteration ($p < 0.001$), diaphragm stripping ($p < 0.001$), diaphragm resection ($p < 0.001$) and gross pelvic or para-aortic lymph nodes ($p = 0.006$) when compared to cases in which splenectomy was not required. Regarding the intraoperative and postoperative outcomes, patients in whom splenectomy was performed had a significantly longer operative time (238 minutes versus 192 minutes, $p = 0.004$), a higher blood loss (1663 ml versus 1167 ml, $p = 0.001$), a higher number of transfused red blood cells (5.3 units versus 3.2 units, $p = 0.002$) and a longer hospitalization (16.1 days versus 12.2 days, $p = 0.001$). However the rates of postoperative complications and 30 days mortality were similar between the two groups. When it comes to the long term outcomes, patients requiring splenectomy had a median overall survival rate of 56.4 months and an estimated 5 year survival of 48% while cases in which splenectomy was not necessary had a median survival rate of 76.8 months and an estimated 5 year survival rate of 58%. However these data did not reach statistical significance ($p = 0.4$). The authors underlined that, although a less favourable outcome was observed among patients submitted to splenectomy when compared to those who did not necessitate it, the presence of splenic involvement should not be considered an indicator of a biologically aggressive disease which could contraindicate the surgical approach. The authors also considered that a stratification of the overall survival according to the type of splenic involvement (contiguous spread of the omental disease, confluent metastases, parenchymatous or lymphatic hilar involvement) could not be feasible due to the small number of cases in each subgroup and suggested that a large multi-institutional prospective observational study is needed to determine whether there are prognostic differences between the hematogenous, peritoneal and lymphatic pattern of spread [41].

DIFFERENCES IN TERMS OF PROGNOSIS ACCORDING TO THE PATTERN OF SPREAD

Once it has been demonstrated that the presence of parenchymatous liver metastases is a poor prognostic factor compared to peritoneal seeding and was considered as an inclusion criteria of FIGO stage IV disease, attention was focused to determine if the presence of other parenchymatous lesions should also be considered as a criterion of FIGO stage IV disease. One of the first authors which suggested that FIGO stage IV should be extended in order to include parenchymatous splenic lesions was J. L. Nicklin in 1995. The author conducted a study on 18 patients submitted to splenectomy as part of primary cytoreduction for advanced stage ovarian cancer between 1989 and 1994; among these cases, three patients were found to have splenic parenchymatous lesions. Due to the poorer outcome of these patients, the authors proposed an extension of FIGO classification in order to include splenic parenchymatous metastases as a criterion for stage IV disease. In the meantime the reported rates of postoperative complications enabled the authors to consider that splenectomy should be performed only in selected cases [42].

Another study in which the authors investigated if a difference in terms of survival should be expected according to the pattern of splenic involvement was conducted by Ayhan et al. The authors reported a series of 34 patients submitted to cytoreductive surgery to < 1 cm residual disease over 12 years in whom splenectomy was performed as part of primary debulking effort [20]. Among these cases the hematogenous pattern of spread was incriminated in 18 cases. Although patients with splenic metastases reported a trend to a poorer prognosis when compared to those who did not have splenic involvement this fact did not reach statistical significance ($p > 0.05$) and the authors concluded that splenectomy should be performed whenever is needed in order to maximize the cytoreductive effort even if parenchymatous lesions are present. The authors reported a postoperative morbidity rate of 29.4% and a 30-days postoperative mortality rate of 8.8%, none of the complications being directly related to the splenectomy procedure [20].

The first study which came to demonstrate that parenchymatous splenic metastases is an independent poor prognostic factor and should be considered as a criterion for FIGO stage IV of disease is the one conducted by Eduard Tanner and published in 2013 [18]. The study involved 576 patients submitted to cytoreductive surgery for FIGO stage IIIB-IV at Memorial Sloan Kettering Cancer Center between 2001 and 2010. Splenectomy was performed in 97 patients while optimal cytoreduction (defined as residual disease as less than or equal to 1 cm) was achieved in 87.6% of them. The histopathological studies of the specimens revealed the presence of parenchymatous lesions in 20.8% of cases, capsular lesions in 67% of cases, splenic hylum in in 47.4% of cases and attached fat in 69.1% of cases. Among the patients with parenchymatous lesions, six of them had other evidence of stage IV disease: hepatic parenchymatous metastases in three cases, supradiaphragmatic adenopathy in two cases and malignant pleural effusion in one case. Patients requiring splenectomy were more likely to be diagnosed in an advanced stage of the disease ($p = 0.014$), including bulky upper abdominal tumors ($p < 0.0001$). In the meantime patients in whom splenectomy was performed were more likely to necessitate other visceral resection such as: rectal resections ($p < 0.0001$), colic resections ($p < 0.0001$), distal pancreatectomies ($p < 0.0001$), hepatic resections ($p < 0.0001$), or diaphragmatic resections ($p < 0.0001$). In order to quantify the complexity of the surgical

procedure the authors used the Surgical Complexity Score introduced by Aletti; according to this score, the patients were classified into low (≤ 3), intermediate (4-7) and high (> 7) complexity scores. Based on this classification, patients submitted to splenectomy were more likely to be considered as having a high complexity score ($p < 0.0001$). When studying the long term outcomes, cases in which a complete cytoreduction was achieved had a significantly better outcome (with a reported progression free survival of 26.3 months and an overall survival of 69.7 months) when compared to those with residual disease < 1 mm (with a reported progression free survival of 16.5 months and an overall survival of 45.7 months) and to those with residual disease > 1 mm (with a reported progression free survival of 12.7 months and an overall survival of 35.3 months). The presence of parenchymatous splenic metastases was another poor prognostic factor, inducing a 21 months decrease in overall survival (the reported overall survival was 28.5 months for patients with parenchymatous lesions versus 49.9 months for cases in which the hematogenous splenic involvement was not present). Other prognostic factors which reached statistical influence in univariate analysis were the age at diagnosis ($p < 0.0001$), preoperative albumin levels ($p < 0.0001$), FIGO stage ($p = 0.001$), histopathological subtype ($p = 0.028$), presence of bulky upper abdominal disease ($p < 0.0001$), the absence of residual disease ($p < 0.0001$), and association of intraperitoneal chemotherapy ($p < 0.0001$). In multivariate analysis the presence of parenchymatous splenic lesions maintained a significant association with a decreased overall survival (OR=0.506; 95% CI, 0.272–0.944) [18].

Another study conducted on this issue involved patients with advanced stage ovarian cancer submitted to splenectomy at the moment of primary cytoreduction in „Dan Setlacec” Center of Gastrointestinal Disease and Liver Transplantation, Fundeni Clinical Institute, Bucharest [43]. Sixty-six patients were eligible for the study, in 55 cases the upper abdominal tumor burden being limited to the spleen while in the other 11 cases bulky abdominal disease being reported. Preoperatively 47 patients were diagnosed in FIGO stage IIIC while the other 19 cases were diagnosed in FIGO stage IV. The most often associated visceral resections included colorectal resections (37 cases), diaphragmatic resections (9 cases), gastric resections (9 cases), distal pancreatectomies (3 cases) and atypical hepatectomies (1 case). The histopathological studies of the specimens described a hematogenous pattern of spread in 19 cases, capsular involvement in 35 cases and hilar involvement in 12 cases. The median hospital in stay was 12 days while the main postoperative complications were pancreatic leakage (in four cases), abdominal abscess (in four cases, two of them necessitating reoperation), pleural effusion (three cases), bronchopneumonia (three cases) and neurologic disorders (three cases). The overall morbidity rate was 30% while the 30-day postoperative mortality rate was 7%; death occurred in five cases: two due to abdominal abscess (originating from an enteral anastomosis in one case and pancreatic leakage in the other case), one case due to a severe bronco-pneumonia, one patient developed a cerebral ischemic stroke, while the fifth patient (with important preoperative cardiac and respiratory dysfunctions) developed a severe uncontrollable metabolic acidosis leading to a multiple organ failure. The authors compared the results to a control group including 272 patients with advanced stage ovarian cancer submitted to cytoreductive surgery in the same period of time and by the same surgical teams but in whom splenectomy was not necessary. The rates of postoperative morbidity and 30 days mortality were similar between the two subgroups: while the postoperative morbidity was 30% among patients submitted to splenectomy and the 30 days postoperative mortality rate was 7%, in the control group which did not necessitate

performing a splenectomy, complications developed in 27% of cases and the early postoperative mortality rate was 5%. Similarly to Tanner's study, a significant difference in terms of survival was obtained between the three patterns of spread: while patients diagnosed with peritoneal seeding reported an overall survival of 58.4 months, patients with parenchymatous lesions had a median overall survival of 24.5 months ($p = 0.0126$); in the meantime the overall survival of cases diagnosed with hilar involvement was 40.6 months. When studying the differences in terms of survival between hilar and parenchymatous lesions and respectively hilar versus peritoneal seeding no significant difference was obtained ($p = 0.362$ and respectively $p = 0.457$). However the study demonstrated the feasibility of the procedure and demonstrated that the presence of hematogenous splenic involvement is an independent negative prognosis factor [43].

SPLENECTOMY AS PART OF CYTOREDUCTION FOR RELAPSE OVARIAN CANCER

After demonstrating the benefits in terms of survival after splenectomy at the time of primary cytoreduction for advanced stage ovarian cancer, studies went even further and tried to demonstrate the feasibility of the procedure as part of secondary and even tertiary cytoreduction. The main studies investigating this issue are summarized in Table 2.

In the study conducted by Hanprasertpong et al. six patients were submitted to splenectomy as part of interval debulking surgery and secondary cytoreduction respectively [49]. Among the three patients submitted to splenectomy as part of secondary cytoreduction in two cases an isolated splenic recurrence was diagnosed while in the third case the splenic lesion was associated to an inguinal lymph node metastasis.

The postoperative course was uneventful in all cases, splenectomy being well tolerated. The histopathological findings revealed the presence of parenchymatous splenic lesions in two cases and a capsular lesion in the third case. When it comes to the long term survival, none of the patients presented evidence of recurrent disease at the moment of ending the study [49].

In a more recent study, twenty-eight patients submitted to splenectomy at the time of secondary, tertiary and even quaternary cytoreduction were introduced [50]. All cases were submitted to surgery in the same center ("Dan Setlacec" Center of Gastrointestinal Disease and Liver Transplantation, Fundeni Clinical Institute, Bucharest) between 2002 and 2014. Splenectomy was performed at the time of secondary cytoreduction in 21 cases, at tertiary cytoreduction in six cases and at quaternary cytoreduction in one case. In all cases the specimen of splenectomy was sent to histopathological study in order to determine if the splenic involvement had a peritoneal, hematogenous or lymphatic origin. At the time of secondary cytoreduction the main associated visceral resections consisted of colic resections (42.86% of cases), rectosigmoidian resections (33.33% of cases), distal pancreatectomy (19.05% of cases), atypical hepatectomy (14.29% of cases) and partial frenectomy (14.29% of cases). The histopathological studies revealed a hematogenous pattern of spread in 42.85% of cases and peritoneal lesions in 52.38% of cases, while the hilar involvement was reported in a single case.

Table 2. Splenectomy as part of debulking surgery in relapsed ovarian cancer

Author	Period of the study	Year of publishing the study	Type of cytoreduction	No. of cases	No. of performed splenectomies (%)	R0 definition	R0 resection (%)	Postoperative complications	Splenectomy related complications	30 days post-operative mortality
Fagotti et al.[44]	May 2005-September 2008	2009	secondary	25	8 (32%)	No visible residual disease	92%	Overall: 44%; severe complications: 28%	NR	0
Schorge et al.[45]	January 1998-January 2008	2010	secondary	40	4(10%)	No residual disease	55%	23% - severe complications	NR	0
Petrillo et al.[46]	January 1995-December 2010	2013	secondary	73	4(5.4%)	1 cm	100%	NR	NR	NR
Tang et al. [47]	May 1999-November 2010	2013	tertiary	83	2 (2.4%)	Microscopic residual disease	34.9%	15%	NR	0
Magrina et al. [48]	January 2006-December 2010	2013	secondary	52	5 (9.6%)	No visible residual disease	75%	36.5% (overall complication rate)	NR	0

The median duration of hospitalization was 14 days (range 2-89 days). Early postoperative complications were reported in six cases, in half of them re-operation being needed; in one case re-operation was imposed by a high-flow enteral fistula, in the second case the indication of re-operation was given by an unresponsive to conservative treatment pancreatic fistula while in the third case early postoperative hemoperitoneum occurred. The early postoperative mortality rate was 9.5%; death occurred in two cases, due to uncontrolled septic shock in one case and haemorrhagic shock with disseminated intravascular coagulopathy in the second case. Although it did not reach statistical significance, the median overall survival of patients with peritoneal seeding was longer when compared to cases with parenchymatous lesions (35 months versus 12 months, $p = 0.2$). When it comes to patients submitted to splenectomy in the setting of tertiary cytoreduction, the main associated visceral resections were: colic resections (in 3 cases), rectosigmoidian resections (in two cases), distal pancreatectomy (in one case) and atypical hepatectomy (in one case).

The histopathological studies revealed a peritoneal pattern of spread in four cases while in the other two cases the hematogenous route was incriminated, the splenic metastases being entirely surrounded by normal parenchyma. Postoperatively two patients developed complications – an abdominal abscess and a biliary fistula, both cases being successfully managed conservatively. The long term outcomes revealed an improved survival for patients with peritoneal seeding (21 month) versus parenchymatous lesions (4 months). However, the results were not statistically significant ($p = 0.08$). As for the patient submitted to splenectomy as the time of the third relapse, quaternary cytoreduction was performed at 102 months after the initial diagnosis and also associated an atypical hepatectomy, partial gastrectomy and extended pelvic resections for a large pelvic recurrence. The histopathological studies revealed a hematogenous liver lesion associated with a peritoneal splenic seeding. The postoperative outcome was uneventful; however the patient died of disease 20 months after quaternary cytoreduction.

This study came to underline that also not statistically significant, a poorer outcome should be expected in patients with parenchymatous lesions at secondary and even tertiary cytoreduction. However, splenectomy was safely associated whenever it was needed in order to maximize the debulking effort [50].

THE ROLE OF LAPAROSCOPIC SPLENECTOMY IN ADVANCED STAGE AND RELAPSED OVARIAN CANCER

In order to improve the early postoperative outcome, to provide a faster recovering and secondarily a more rapid association of adjuvant chemotherapy, attention was focused in performing laparoscopic resections for advanced stage and recurrent ovarian cancer. The first hand-assisted splenectomy for isolated splenic metastases was first reported in 1998 by Klingler demonstrating the feasibility of the procedure [51].

In the study conducted by Dennis Chi et al. the authors included six patients submitted to laparoscopic or hand assisted splenectomy between 1996 and 2005; in five of the six cases laparoscopic or hand assisted resection was performed while in the sixth case conversion to laparotomy was imposed by the presence of peritoneal carcinomatosis [52]. In four of the six cases the histopathological examinations confirmed the presence of splenic tumoral

involvement while in the other case a benign splenic cyst was found. In one of the cases residual tumor < 1 cm was reported, all the other cases being cytoreduced to no residual disease. The estimated blood loss ranged between 50 and 300 ml while the postoperative hospitalization ranged between 3 and 5 days. Postoperatively all five cases in which recurrent disease was diagnosed were submitted to adjuvant therapy with platinum based salts and taxanes (in four cases) while the fifth patient underwent aromatase inhibitor therapy. At 2084 months after surgery all patients were free of any recurrent disease. The study came to demonstrate the effectiveness of the procedure and underlined the fast recovery of the patient; however the authors considered that this procedure should be performed only by specialized surgeons and in selected cases [52].

In the meantime, Pedro Ramirez published a paper focusing on the technique of open versus totally laparoscopic splenectomy in cases with advanced or recurrent ovarian cancer. The author demonstrated the feasibility of total laparoscopic splenectomy by a lateral approach using a four ports technique. After complete mobilization, the specimen of splenectomy is placed in an Endobag and extracted through the 12 mm trocar after extending the incision line. According to the same author after laparoscopic splenectomy a pancreatic leak rate of 6% is expected while the thromboembolic events occur in up to 10% of cases [53].

In another similar study Fagotti introduced 10 patients with relapsed ovarian cancer who were submitted to laparoscopic or robotic surgery associated with intraperitoneal hypertemic chemotherapy (HIPEC) for isolated recurrences [54]. In seven cases debulking was performed on the laparoscopic route while in the other three cases a robotic approach was chosen. As for the chosen chemotherapeutic agent for HIPEC, nine patients received cisplatin while the tenth patient received oxaliplatin. In two cases splenectomy was needed while in the other eight cases location of the recurrence necessitated radical omentectomy or selective splenectomy. The operative time ranged between 95 and 140 minutes while the estimated blood loss ranged between 50 and 100 ml. All patients were discharged after 3-7 days while systemic chemotherapy was administrated after a median interval of 21 days (19-32 days). A single patient developed postoperative complications consisting of a low frequency atrial fibrillation. When it comes to long term outcomes, no recurrence or death was reported after 10 months (range 6-37 months). The authors demonstrated the safety and efficacy of laparoscopic surgery for isolated relapse from ovarian cancer in association with HIPEC, a shorter convalescence interval and a faster administration of systemic chemotherapy being achieved [54].

One of the most suggestive studies regarding the benefits of minimally invasive surgery in relapsed ovarian cancer comes from Javier Magrina et al. and involved a retrospective analysis of 52 patients submitted to secondary cytoreduction for relapsed ovarian cancer at Mayo Clinic Arizona between January 2006 and December 2010 [48]. Among these cases laparoscopic resection was performed in 9 cases, robotics in 10 cases, while the other 33 patients were benefited from a classic approach. Splenectomy was performed in 11.1% of patients submitted to laparoscopy and 12.1% of patients submitted to laparotomy. The perioperative outcomes were similar between the three subgroups in terms of operating time, rate of complete debulking surgery, intra- and postoperative complications, while the estimated blood loss and postoperative hospital in stay were significantly lower in the minimally invasive subgroup. In the meantime there was no significant difference in regard to

the long term outcomes, the reported overall survival being similar among the three subgroups [48].

Association of Pancreatic Resections to Splenectomy as Part of Cytoreductive Surgery in Advanced Stage and Relapsed Ovarian Cancer

In a significant number of cases the presence of the bulky left quadrant abdominal disease will force the surgeon to perform multiple visceral resections en bloc with the tumor in order to achieve negative resection margins and an R0 resection. One of the most frequent associated visceral resection to splenectomy remains distal pancreatectomy [14]. Although initially it has been considered that a pancreatic resection predisposes to an unacceptable risk regarding the postoperative morbidity rate, progression achieved in hepat-bilio-pancreatic surgery offered the possibility to safely include pancreatic resection as part of debulking surgery for advanced and relapsed ovarian cancer. However, at this moment the reported experience regarding pancreatic surgery as part of debulking is still limited, most of the reported cases including small series of patients.

In the study conducted by Pieluigi Benedetti Panici involving 121 patients with advanced stage ovarian cancer distal pancreatectomy was associated in 16 cases while splenectomy was performed in 48 cases. After performing an aggressive surgical approach the rate of complete cytoreduction (defined as no residual disease) was 75.1%. When studying the short term outcomes, the authors reported that performing pancreatic resection was associated with a longer length of hospitalization in both univariate and multivariate analysis. In the meantime pancreatic surgery was associated with the higher rate of postoperative complications, with a reported rate of pancreatitis and abscess formation secondary to a pancreatic leak of 13% among cases submitted to pancreatic resections [33].

Most often complications related to pancreatic surgery are related to the exocrine pancreatic secretion as pancreatic leaks and their rate ranges between 30-60% while the mortality rate is up to 5% [55-57]. However, the rate of reported pancreatic leaks widely varies in literature data due to the absence of a standard definition of the pancreatic leak. While Rodriguez *et al.* defined pancreatic fistula as a daily output of at least 30ml/day with amylase levels three times higher compared to amylase serum levels after the fifth postoperative day [57], Grobmyer defined it as clinical signs or radiological confirmation of a collection with increased levels of amylase (more than 50 ml/day) beyond the fifth postoperative day [58]. The first standardized definition came from the International Study Group of Pancreatic Fistula: according to their opinion, pancreatic leak was defined as a left upper quadrant fluid collection present after the third postoperative day with a fluid amylase level >3 times the level of serum amylase [59].

In order to determine the incidence and management of pancreatic leaks after splenectomy en bloc with distal pancreatectomy during primary cytoreduction Siobhan Kehoe *et al.* conducted a study on 17 patients; all cases were submitted to splenectomy en bloc with distal pancreatectomy as part of primary cytoreduction between January 2001 and December 2006 [60]. In the meantime splenectomy without pancreatic resection was performed in other 24 cases. Pancreatic leaks were defined accordingly to the International Study Group of Pancreatic Fistula. Optimal cytoreduction was defined as residual tumor of less than 1 cm. In all cases distal pancreatectomy was performed for left quadrant bulky disease invading the

spleen and the splenic hylum, inseparable from the pancreatic tail. In all cases the pancreatic tail was transected using a vascular stapler while the reinforcement of the stapler line by oversewing remained at the surgeon's discretion. In 53% of cases resection to no gross residual disease was achieved while in other 41% of cases optimal cytoreduction was performed; in a single case the remnant tumoral volume was larger than 1 cm. Postoperatively 24% of the patients developed pancreatic leaks at a median time of 9 days after resection. In three cases pancreatic leaks developed in the early postoperative period (within the first 10 days postoperatively) while in the fourth case the pancreatic leak was diagnosed in the 66th postoperative day, after re-admission for abdominal pain; the biological tests showed an increased number of leukocytes while the imagistic studies revealed the presence of a multiloculated collection surrounding the pancreas which was successfully drained by percutaneous route; a therapy with somatostatin, bowel rest and total parenteral nutrition were also instituted with good outcomes, the patient being able to retake the oral diet two weeks after drainage. In regard to the histopathological studies, the authors reported parenchymatous splenic metastases in six cases, parenchymatous pancreatic lesions in one case and peripancreatic tumoral involvement in 12 cases; however all patients in whom pancreatic leak was found had a peri-pancreatic tumoral involvement. The authors concluded that spleno-pancreatectomy should be performed in metastatic gynaecological cancers although pancreatic leaks represent a relative complication after distal pancreatectomy [60].

In the study conducted by Bacalbasa et al. at "Dan Setlacec" Center of Gastrointestinal Diseases and Liver Transplantation, Fundeni Clinical Institute, Bucharest six patients submitted to spleno-pancreatectomy were included. The patients were submitted to pancreatic resections at the moment of primary cytoreduction (one case), secondary cytoreduction (four cases) and tertiary cytoreduction (one case). During the early postoperative period two patients developed pancreatic fistulas; both cases were submitted to pancreatic resections at the moment of secondary cytoreduction. In one case the pancreatic fistula was successfully treated by conservative approach, while in the second case reoperation was needed. There was no complication related to splenectomy. In all cases complete cytoreduction to no visible residual disease was achieved. The 30-days postoperative mortality was 0. The patient submitted to spleno-pancreatectomy during primary cytoreduction was diagnosed with relapsed ovarian cancer at 54 months follow up and was proposed for secondary cytoreduction at the time of ending the study; the median overall survival for patients submitted to distal pancreatectomy was 36.38 months while the patient submitted to spleno-pancreatectomy at the moment of tertiary cytoreduction died of disease 10 months later. The study came to demonstrate the benefits of extended upper abdominal resections including splenopancreatectomy in advanced and relapsed ovarian cancer in order to achieve a complete resection and secondarily, a benefit in terms of survival [61].

CONCLUSION

Although splenic involvement is not a common situation in the setting of advanced stage and relapsed ovarian cancer, large studies came to demonstrate the safety and effectiveness of splenectomy as part of debulking surgery. Moreover, a difference in terms of survival between the different patterns of spread has been recently demonstrated, suggesting the

possibility to include hematogenous splenic metastases among the inclusion criteria for FIGO stage IV. When it comes to the benefit of multiple visceral resections, distal pancreatectomy was successfully associated to maximize the debulking effort.

ABSTRACT

Ovarian cancer is one of the most aggressive gynecologic malignancies and represents a major cause of death for women worldwide. This aggressive behavior is especially related to the fact that most patients are diagnosed in an advanced stage of the disease when disseminated tumoral burden is already present. Although the intraperitoneal route seems to be the most common pattern of spread, ovarian cancer can also develop distant metastases by hematogenous route and throughout lymphatic channels, the most commonly affected sites by hematogenous spread including the lungs and liver. Historically, patients with liver involvement have been considered as having a systemic, uncontrollable disease and were considered as candidates for supportive care or palliative chemotherapy.

Although the presence of liver metastases at the moment of diagnosis is usually associated with an altered tumor biology and aggressive disease, there was no convincing evidence that cytoreduction in the presence of liver metastases is less efficacious. Starting from this hypothesis, hepatic resection for ovarian cancer liver metastases has been proposed.

However, at this moment it is estimated that the number of patients submitted to liver resection for hepatic metastases from gynecological cancer represent less than 1% of the total resected liver metastases, the role of surgery in patients with ovarian cancer liver metastases being still in question. The main reason for this paucity of hepatectomies in ovarian cancer liver metastases is related to the fact that usually these kinds of tumors develop liver metastases in the settings of obvious systemic or regional dissemination which is not suitable for a complete macroscopic resection. Patients presenting resectable, isolated and limited to liver metastases are rather an exception than a rule in

the setting of ovarian cancer. However this small subgroup of patients with isolated hepatic lesions has been initially considered to suit best to liver resection.

According to this principle, initially the main indication for resection in ovarian cancer liver metastases was the presence of solitary liver lesions with no extrahepatic tumoral burden as the best results in terms of survival had been obtained in such cases. More recently, it has been demonstrated that the presence of extrahepatic tumoral burden does not represent a significant prognostic factor for a poorer outcome in all patients and allowed to identify the subsets of patients with extrahepatic tumor burden who could benefit most from liver resections.

A crucial step in studying the long term outcomes after liver resection for ovarian cancer hepatic metastases was demonstrating the different outcomes between the two distinct patterns of hepatic involvement: peritoneal and hematogenous spread. Metastases originating from peritoneal seeding with parenchymatous invasion of at least 2 cm were classified as peritoneal lesions while lesions entirely surrounded by liver parenchyma were considered to have hematogenous origins. Significant differences in terms of survival between patients with peritoneal versus hematogenous lesions submitted to complete resections were observed. Based on these findings, it has been largely accepted that the presence of peritoneal seeding involving the liver included the case in FIGO stage IIIC while the presence of hematogenous liver involvement should be classified as FIGO stage IV.

When it comes to the role of liver resection as part of secondary or even tertiary cytoreduction, literature data is even scarcer, the presence of liver metastases being considered for long time as an exclusion criterion when establishing whether a patient is a candidate for optimal cytoreduction at the moment of surgery for recurrent disease. In time, improved understating of hepatic anatomy in association with the improvement of surgical techniques and postoperative care transformed hepatic resection in a more frequent associated surgical procedure in serial resections for ovarian cancer relapse. Once liver resection has been successfully associated as part of cytoreduction for relapsed ovarian cancer, attention was focused on determining other potential prognostic factors which might influence survival such as initial FIGO stage, disease free survival or histopatologic subtype of the tumor.

This chapter focuses on the subject of liver resection as part of cytoreductive surgery for advanced stage or relapsed ovarian cancer. The influence of different patterns of spread, the safety and effectiveness of performing anatomical or extended liver resections are also presented.

INTRODUCTION

Ovarian cancer remains one of the most common and aggressive malignancies worldwide, with an estimated incidence of 225,500 new cases per year and a reported mortality of 140,200 deaths per year [1]. Unfortunately, the majority of patients are diagnosed in an advanced stage of the disease when disseminated lesions are already present; most of these cases will experience recurrent disease; only 20-25% of patients being expected to experience a long term survival despite an initial good response to primary therapeutic strategy [2-4]. However, in the last decades the reported survival even in patients diagnosed in an advanced stage of the disease significantly increased due to the progressive incorporation of more extended surgical resections in order to maximize the debulking effort [5]. When it comes to the optimal residual disease, the definition of optimal cytoreduction has modified from remnant tumor < 1cm to no gross residual disease [5]. The redefinition of

optimal residual disease was proposed by Chang and Bristow and was based on the results of Bristow's meta-analysis conducted on 6885 patients with advanced stage ovarian cancer. The author demonstrated that each 10% increase in the proportion of patients undergoing maximal cytoreduction was associated with a 5.5% increase of the median cohort survival time. The authors concluded that one of the strongest factors influencing the long terms outcomes was performing a maximal cytoreductive surgery [6]. However, in patients diagnosed in an advanced stage of the disease, presenting disseminated lesions multiple visceral resections might be needed. In cases with pelvic extension association of surgical procedures such as pelvic peritonectomy, rectosigmoidian resection, colic or enteral resections or even urinary tract resections have been successfully implemented in the armamentarium of the oncologic gynecologist increasing the rate of resection to no visible residual disease [7-10]. Although these procedures have been introduced as part of the standard surgical procedures which might be needed in order to achieve a complete cytoreduction, the percentage of patients benefiting from a maximal debulking effort widely varies in the literature data from 15% to 85% [6]. It has been advocated that studies in which the reported rate of optimal cytoreduction surpasses 50% usually incorporate extensive upper abdominal resections [11-13]. Chi et al. demonstrated that association of upper abdominal extended resections leads to a significant improvement of disease free survival and overall survival, so they recommended that surgeons should consider including these therapeutic gestures as part of the standard treatment in patients presenting upper abdominal involvement [14].

When it comes to hepatic metastases in ovarian cancer, the presence of liver involvement at the time of diagnosis or during the evolution of the disease is usually considered as a poor prognosis factor with devastating effects on the long term outcomes [15].

MECHANISMS OF LIVER INVOLVEMENT IN ADVANCED STAGE AND RELAPSED OVARIAN CANCER

When it comes to the most common patterns of spread in advanced stage ovarian cancer, it has been widely demonstrated that the main pathways of spread are represented by the peritoneal route, followed by lymphatic and hematogenous route. While the presence of peritoneal spread is usually conditioned by the apparition of the epithelial –to – mesenchymal transition in association with the presence of growth factors and cytokines, the hepatic involvement via hematogenous route usually occurs via portal flow [16, 17]. However, the presence of ovarian cancer liver metastases is common events since Rose et al. reported in their study that nearly one half of the patients with ovarian cancer have liver metastases at the time of death. The study presenting the autopsy findings in 428 patients with various histological subtypes of ovarian cancer also reported that while the peritoneum was most commonly involved (in up to 100% of cases), lymph node metastases were reported in up to 60% of cases [17]. In the study conducted by Cormio et al. the liver was reported as the most common site of distant metastases [15]. The different outcomes reported after liver resections of peritoneal versus hematogenous liver metastases is also suggested by the inclusion of the two patterns of spread as two separate criteria in FIGO classification: while the presence of capsular hepatic lesions is considered as IIIC stage of the disease while the presence of hematogenous lesions (defined as hepatic parenchymatous lesions) is considered as an

inclusion criteria for FIGO stage IV of disease [18]. In conclusion, a clear distinction between the different pathways of liver involvement needs to be made in all cases.

SAFETY AND EFFECTIVENESS OF HEPATIC RESECTIONS IN OVARIAN CANCER LIVER METASTASES

Initially it has been considered that liver resection is not justified due to the fact the hepatic involvement usually develops in the context of a systemic disease and therefore, systemic chemotherapy should be the treatment of choice [19-21]. However, the reported success after hepatic resections in colorectal and neuroendocrine malignancies quantified by increasing the rate of long term survivors up to 25% at ten year follow up encouraged the surgeons worldwide to study the effectiveness and benefits in long term outcomes for liver resection in non-colorectal non-neuroendocrine liver metastases [19-23]. Although the groups of patients involved in these studies are small in number and heterogeneous in regard to the primary tumor, the general conclusion is that hepatic resection could improve the long term outcomes [21-23]. Among cases included in these studies, patients with advanced stage or relapsed ovarian cancer were involved and a benefit in terms of survival was achieved. The most important studies focused on this issue are summarized in Table 1.

All these reported results showing increased rates of survival after resection of liver metastases enabled the surgeons worldwide to include it in the standard treatment for hepatic metastases from other primaries including gynecological cancers.

In the study conducted by Sarah Kamel et al. the authors introduced 87 patients diagnosed with liver metastases from gynecological malignancies submitted to hepatic resections at John Hopkins Hospital between 1990 and 2010. Most patients included in the study had a primary tumor located in the ovary (67 cases, 77%) and were classified with FIGO stage III disease. Other involved primaries were uterus/endometrium (in 17% of patients), cervix (in 4% of cases) and fallopian tube (in 2% of cases). The main surgical procedure consisted of total hysterectomy with bilateral adnexectomy (81%), concurrent lymph node dissection (61%) and peritoneal debulking (81%). Up to 34% of cases were found to have positive lymph nodes.

Synchronous liver involvement was reported in 30 patients (34% of cases) while in the other 57 patients metachronous lesions were found after a median disease free interval of 25 months.

Among patients with synchronous liver metastases 24 cases (80%) were submitted to concomitant liver resections. Among patients diagnosed with metachronous liver lesions 45 patients had been submitted to neoadjuvant chemotherapy; furthermore, 23 patients were submitted to liver resections. When studying the completeness of resection, negative resections margins were seen in 63% of cases, while 15% of specimens revealed microscopic disease on the specimen's margins; in a single case macroscopic residual disease was reported. The postoperative mortality rate was 0. Recurrence was found in 39 cases after a median follow up of 13 months: in six cases the recurrence was limited to the liver, in 13 cases only an extrahepatic recurrent disease was found, while in the other 18 cases both intrahepatic and extrahepatic recurrences were reported; in other two cases the site of recurrence remained unknown.

Table 1. Studies conducted on the issue of hepatic resections in non-colorectal non-neuroendocrine liver metastases including subjects with ovarian cancer

Author, year of the study	Period of the study	No. of cases	No of patients with ovarian cancer (%)	5-year overall survival of the entire cohort	Median survival after resection of cases with ovarian primaries (months)
Slotta et al. 2014 [21]	7 years	101	5 (15.84%)	30%	15.84
Reddy et al. 2007 [22]	1995-2005	82	11 (13.4%)	37%	NR
Martel et al. 2105 [24]	1990-2012	52	3 (5.7%)	58%	89.9
Lendoire et al. 2007 [25]	1989-2006	106	14(13.2%)	19%	NR, 5-year OS for genitor-urinary tumors (renal, ovarian) 30%
Adam et al. 2006 [26]	1983-2004	1452	65 (4.47%)	36%	98

Of the six patients diagnosed with intrahepatic recurrent disease three cases were submitted to re-operation. The median overall survival after resection of liver metastases with ovarian origin was similar to the other non-ovarian primaries (21 versus 22 months respectively, $p = 0.53$). Although patients diagnosed with parenchymatous lesions had a poorer outcome, this fact did not reach statistical significance ($p = 0.12$) [27].

One year later Jose Ramia et al. published a literature review suggestively entitled: "Liver Metastases from Gynecological cancers: Time to Resection?" in which the author included the published articles between 1990 and 2011 based on a PubMed Search. A total of 20 articles including case-reports were reviewed; however the authors referred only to hematogenous metastases. When it came to ovarian cancer, liver resection was mainly proposed for isolated lesions, the presence of concomitant extra-hepatic burden being even considered as an absolute contraindication by some authors [28, 29]. However, most studies considered that primary debulking surgery followed by adjuvant chemotherapy is the treatment of choice, although relapse might occur [30-32]. Moreover, a second debulking surgery has been proposed, especially in patients with a reported disease free survival of at least 12 months. Although an important percentage of patients is expected to be submitted to secondary cytoreduction, liver resection is performed only in a low percentage of cases ranging between 0 and 9%. When it comes to prognostic factors, negative resection margins, the absence of extrahepatic burden, slow-growing tumors, a longer disease free survival (> 12 months) and a good clinical status were associated with improved survival [33].

LIVER RESECTION AS PART OF UPPER ABDOMINAL SURGERY IN ADVANCED STAGE AND RELAPSED OVARIAN CANCER

In an attempt to improve the rates of complete cytoreductive surgery Dennis Chi et al. introduced in the therapeutic armamentarium extensive upper abdominal surgical procedures as part of primary cytoreduction for advanced stage ovarian cancer from 2001. In order to demonstrate the feasibility and safety of these procedures, the authors compared the results with those obtained before the year of 2001 in the same hospital. The first study group consisted of 168 patients submitted to cytoreductive surgery between 1996-1999 while the second group consisted of 210 patients submitted to cytoreductive surgery between 2001 and 2004. Both study groups included patients with FIGO stage IIIC and IV; however, upper abdominal surgery was performed only in the second group. Extended upper abdominal surgery included diaphragmatic peritonectomy and/or resection, splenectomy, distal pancreatectomy, cholecistectomy, hepatectomy and porta hepatis tumor resection. Optimal residual disease was defined as no residual tumor larger than 1 cm. The two subgroups were similar in regard to age at diagnosis, tumor stage, tumor grade or clinical status according to the American Society of Anesthesiologists class. Among the patients submitted to extended upper abdominal resections, hepatectomy was performed in 13 patients (6% of cases) while resection of porta hepatis lesions was performed in 11 patients (5% of cases). The rate of complete cytoreduction was significantly higher among the second group (80% versus 46% in the first group, $p < 0.01$). In the meantime the estimated blood loss, intraoperative transfusion rates, operative time and major complications were more frequently present in the second group. However none of these aspects influenced the administration of adjuvant

chemotherapy while the mortality rate was similar between the two groups (0.6% in the first group versus 0.6% in the second group). When it comes to long term outcomes, the 5 year overall survival rate was 31% in the second group, significantly higher when compared to the first group (with a 5 year overall survival rate of 14%, $p = 0.001$). The reported median overall survival was 54 months for the second group and only 43 months for the first group ($p = 0.03$) [14].

In another similar study focused on the issue of extended upper abdominal resections in patients with stage IIIC and IV ovarian cancer, Eisenhauer et al. introduced 262 patients divided in three groups: the first group included 57 patients who required extended upper abdominal resection to achieve complete cytoreduction, the second group included 122 patients in which upper abdominal procedures were not necessary while the third group included 83 patients with advanced stage disease but who were submitted to incomplete cytoreduction. Among cases submitted to extended upper abdominal procedures liver resection was performed in 9 cases (16%) while porta hepatis tumor was resected in 8 cases (14%). The first group reported a longer operative time and a higher median blood loss while the complication rate was similar between the different groups. In the meantime, although patients from the first group were submitted to the adjuvant chemotherapy later on when compared to the other two groups, similar doses of chemotherapeutic agents were administrated and the response to chemotherapy was significantly improved. As for the long term outcomes, comparable rates of survival were obtained for the first two groups and were significantly higher when compared to the third group (at the end of the study the median overall survival was not yet reached for group 1, was 84 months for group 2 and 37 months for group 3). The similar reported outcomes between the first two groups come to demonstrate the efficiency of extended resections. In the meantime comparable rates of postoperative complications enabled the surgeons to consider that addition of upper abdominal resections is a safe procedure [34].

Once it has been widely demonstrated that completion of the resection is one of the strongest predictors for long term survival, few authors focused on determining the specific involvement sites which could predict the presence of unresectable disease. For example, Francesco Raspagliesli studied the influence of upper abdominal tumor burden involving the omental bursa, lesser omentum, celiac, portal and triad nodes spread as cause of incomplete cytoreduction. A total of 37 consecutive patients with advanced stage ovarian cancer and upper abdomen involvement were introduced in the study: 29 cases were diagnosed with FIGO stage IIIC disease while the other 8 patients were classified as FIGO stage IV. Cytoreduction to no residual disease was achieved in 34 cases, while in the other 3 cases residual disease of 5 mm was reported. The main location of the residual nodules was at the level of hepatic pedicle, demonstrating that the involvement of the areas surrounding the vital anatomic structures in the upper abdomen might still be a reason for incomplete cytoreduction [35].

While most studies focus on the possibility of obtaining a complete cytoreduction and an improved long term survival, only few studies have been conducted on the issue of the early postoperative complications and their predictors. One of the largest studies regarding this subject was conducted by Pierluigi Beneditti Panici and involved 121 patients submitted to 212 surgical procedures including upper abdominal resections. Upper abdominal sites of involvement included: diaphragm (51.2%), the liver (33.5%), the stomach (13.3%), the biliary tract and porta hepatis (19.8%), the spleen (43.8%) and the pancreatic tail (11.6%). The main

performed upper abdominal procedures included diaphragmatic peritonectomies (28.9%), diaphragmatic resections (31.4%), glissonian resections (15.7%), liver resections (13.2%), gastric resections (9.9%), distal pancreatectomies (13.2%), splenectomy (39.6%) and biliary tract surgery (19.8%). In univariate analysis performing diaphragmatic, pancreatic, gastric and splenic resections was associated with longer postoperative hospital in stay. Hepatic surgery was associated with a minimal increase of the length of hospitalization (9.2 days for patients submitted to liver resections versus 8.8 days for cases in which liver resection was not necessary, $p = 0.757$).

Despite this fact, liver surgery was associated with a higher rate of complications. In two cases a severe blood loss was observed after resection of nine and seven respectively liver metastases, while postoperatively hepatic surgery was significantly associated with an increased rate of both overall and severe complications ($p = 0.037$ and $p = 0.004$ respectively). The reported 90 days mortality rate was 0.8%. The authors concluded that extended upper abdominal resections should be performed in selected cases and by selected surgical teams, in centers with a high capacity to manage life-threatening complications [36].

LIVER RESECTION AT THE MOMENT OF PRIMARY CYTOREDUCTION FOR ADVANCED STAGE OVARIAN CANCER

At the time of primary cytoreduction, liver resection for ovarian cancer is most often presented as integrative part of the maximal cytoreductive effort in association with other extrahepatic resections.

In order to evaluate the role of debulking surgery in patients with stage IV ovarian cancer, Bristow et al. conducted a study on 84 patients with a median age at diagnosis of 61 years. Forty-four percents were diagnosed with parenchymal liver metastases while 38% had malignant pleural effusion. Optimal cytoreduction (defined as residual disease < 1 cm) was achieved in 30% of cases and was associated with a median overall survival of 38.4 months, while patients with suboptimal residual disease reported an overall survival of 10.3 months ($p = 0.0004$).

Optimal resection of both intrahepatic and extrahepatic disease was achieved in 16% of cases and reported an overall survival of 50.1 months, significantly higher when compared to patients with optimal extrahepatic disease but suboptimal residual hepatic tumor (with a median survival rate of 27 months) and with those with suboptimal extrahepatic and hepatic disease who had a median overall survival rate of 7.6 months [37].

The benefits of multiple visceral resections in the setting of FIGO stage IIIC and IV ovarian cancer were also reported in the study conducted by Heinz Scholz over a five year period, on 101 patients in Nurnberg, Germany. Among these cases, 54% of patients were submitted to surgery as primary therapeutic option while the other 46% of cases had been previously submitted to neoadjuvant chemotherapy. In all cases cytoreduction to no gross residual disease was attempted and was achieved in 82% of cases submitted to surgery as first therapeutic option and in 85% of cases in which neoadjuvant chemotherapy had been performed ($p = 0.793$).

Partial hepatectomy was performed in 11% of cases while Glisson capsule resection was performed in 39% of cases; the 30 days postoperative mortality rate was 0. Long term

outcomes revealed a median survival of 47 months while the five year survival rate was 33% for the entire group. Patients submitted directly to surgery reported a better outcome in terms of survival comparatively to those submitted to neoadjuvant chemotherapy and interval debulking surgery ($p = 0.046$). The authors demonstrated the effectiveness of debulking surgery even if hepatic metastases are present and revealed the superiority of primary surgical treatment comparatively to interval debulking surgery [38].

Another German study comes from Ulf Neumann and discusses the benefits of liver resections as part of primary cytoreductive surgery in advanced stage ovarian cancer. The study was conducted between 1991 and 2007 and included 70 patients with advanced stage disease submitted to surgery in Charite, Virchow Clinic. Liver resection was performed in 41 out of the 70 patients, the other 29 cases presenting unresectable disease. Additional surgical procedures included total hysterectomy (in 14.3% of cases), bilateral adnexectomy (in 24.3% of cases), omentectomy (in 32.9% of cases), partial colectomy (in 51.4% of cases), partial small bowel resection (in 32.9% of cases), partial gastrectomies (in 5.7% of cases) and partial pancreatectomies (in 4.3% of cases).

In all cases submitted to liver resection a residual tumor volume < 5 mm was achieved. The 3- months postoperative mortality rate was 14.6% in the subgroup submitted to liver resection and 41% in the subgroup in which liver resection was not feasible ($p = 0.025$), while the morbidity rate was similar between the two groups. Regarding the long term outcomes, the median survival rate was significantly higher among patients submitted to liver resection: patients submitted to an R0 resection reported a median survival rate of 42 months while cases in which liver resection was not feasible reported a median overall survival of 4 months ($p < 0.001$).

Other poor prognostic factors were represented by the presence of ascites and bilobular liver metastases. When it came to establishing the predictors of resectability of hepatic metastases, only the presence of ascites was associated with a poorer resectability rate. The authors concluded that liver resection should be part of the standard therapeutic protocol whenever a residual disease of less than 5 mm can be achieved and demonstrated that performing hepatic resections in ovarian cancer liver metastases does not increase the early postoperative mortality rate [39].

THE SIGNIFICANCE OF HEMATOGENOUS HEPATIC METASTASES IN THE SETTING OF ADVANCED STAGE OVARIAN CANCER

Based on the postoperative outcome, liver involvement in advanced stage ovarian cancer is classified as FIGO stage IIIC when peritoneal seeding involving the liver parenchyma is diagnosed and stage IV respectively when hematogenous spread is the pathogenic mechanism. Thus, hepatic hematogenous involvement is based on the postoperative pathologic diagnosis. In an attempt to determine if there is a survival difference between parenchymatous and peritoneal hepatic involvement in cases in which an R0 resection is achieved large studies have been conducted.

In the study conducted by Lim et al. data of 117 patients submitted to primary cytoreduction for advanced stage ovarian cancer with liver involvement were retrospectively reviewed. Sixteen of the 117 patients were diagnosed with parenchymatous lesions and were

included in FIGO stage IV group; however, in two cases the tumors proved to be unresectable and liver surgery consisted only in liver biopsy, confirming the ovarian origin. The remaining 14 cases were underwent hepatic resections and the histopathological studies confirmed the presence of hematogenous liver involvement. In all cases negative resection margins were achieved. The remnant 101 patients were diagnosed with FIGO stage IIIC disease. In the two cases in which liver resection could not be performed, although 3rd line chemotherapy was initiated, the reported survival was of only 9 and 10 months respectively. Among patients diagnosed with FIGO stage IIIC disease 44 cases were submitted to neo-adjuvant chemotherapy. When it comes to the preoperative and intraoperative findings, there were no significant differences regarding the age, histology or grade, median CA 125 levels or the administration of neo-adjuvant chemotherapy. Optimal cytoreduction was achieved in 94% and 93% respectively in patients diagnosed in FIGO stage IIIC and IV while no visible residual disease was reported in 47 and 43% of patients with FIGO stage IIIC and IV respectively. The main types of liver resection included wedge resections in 50% of cases, segmentectomies in 36% of cases and hemi-hepatectomies in 14% of cases. There was no significant difference regarding the operative time, estimated blood loss, transfusion, postoperative hospital stay, largest residual disease or time to adjuvant chemotherapy. No liver-related surgery complication such as bile leakage or bleeding occurred. The most common complications in the both group were febrile morbidity, ileus, pancreatic fistula and pleural effusion. In regard to the long term outcomes, the 5-year overall survival rates were 55% and respectively 51% for the two subgroups ($p = 0.5671$). The authors concluded that if an R0 resection is achieved in cases with parenchymatous lesions, a similar overall survival to cases with peritoneal lesions should be expected and suggested that a possible revision of FIGO classification might be taken in consideration [40].

In a similar study conducted at “Dan Setlavec” Center of Gastrointestinal Disease and Liver Transplantation, Fundeni Clinical Institute, Bucharest 11 patients submitted to liver resection at the time of primary cytoreduction were included. Neoadjuvant chemotherapy was administrated in two cases. Postoperatively the rate of severe complications in 25% patients, all of them being diagnosed with stage IV disease; however, the 30 days postoperative mortality was 0. Although it did not reach statistical significance the overall survival was consistently higher among patients with peritoneal seeding (34.33 months versus 15.63 months, $p = 0.702$) [41].

LIVER RESECTION AS PART OF SECONDARY CYTOREDUCTIVE SURGERY

The benefits of secondary cytoreduction in the setting of relapsed ovarian cancer have been widely demonstrated with maximal effects in cases with a long disease free interval after completion of the primary therapeutic protocol and if isolated recurrences are found at the time of relapse [42]. However, even if multiple recurrences are found at the time of diagnosis, an aggressive surgical approach in order to maximize the debulking effort is perfectly justified in order to improve survival [43-46]. In the study conducted by Niu et al. the authors included both patients with no history of extrahepatic disease as well as patients with extrahepatic burden. Although patients with liver confined disease had an improved outcome

(median overall survival of 41.42 months) when compared to those with both intrahepatic and extrahepatic disease (median overall survival of 36.99 months), the benefit in terms of survival was consistent when compared to the results of the patients submitted to chemotherapy alone [46]. In a similar study conducted by Roh et al. the outcomes of 18 patients submitted to hepatic resections for ovarian cancer liver metastases with the reported results of 25 cases with unresectable liver metastases; although extrahepatic resections were similar between the two groups, in the second subgroup no liver procedure (including surgery, radiofrequency ablation or ethanol injection) was performed. The overall survival rate was significantly improved in the hepatectomy group - 38 months, comparatively to the non-hepatectomy group - 10 months ($p = 0.0232$) [47]. The largest studies conducted on the issue of liver resection at the moment of secondary resection are summarized in Table 2. As for the early postoperative outcomes, improvement of surgical technique of hepatic resections has led to acceptable postoperative rates of liver related surgery complications and an early postoperative mortality rate almost null [51,52]. In the meantime the actual surgical techniques in association with the postoperative management provided the possibility of resecting up to 70% of the liver parenchyma with mortality rates of up to 5% [53]. All these aspects encouraged surgeons to perform more extended resections for liver metastatic disease. When it comes to the long term outcomes, association of liver resection as part of cytoreductive surgery has significantly improved the overall survival. The most suggestive results in regard to the short and long term outcomes are summarized in Table 3.

PROGNOSTIC FACTORS AFTER LIVER RESECTION AT THE MOMENT OF SECONDARY CYTOREDUCTION

Association of Extrahepatic Tumor Burden and Diameter of the Residual Tumor

The strongest predictor for long term survival remains the completeness of the resection. In Bosquet's study optimal cytoreduction was defined as hepatic or extra-hepatic residual disease < 1cm in the greatest diameter was consistently associated with improved survival: the median disease specific survival was significantly higher in patients submitted to optimal cytoreduction when compared to those in which optimal cytoreduction was not feasible: 41,3 months versus 5,7 months, $p < 0.0001$) [42].

Similar results were reported by Kolev et al. at the same cut-off of 1 cm [49]. In the study conducted by Niu et al. involving 60 patients submitted to liver resection for metachronous liver metastases the completion of the resection was achieved by studying the resection margins of the specimen. The absence of tumor involvement on the resection margins was defined as R0 resection and associated a significantly improved outcome when compared to patients with R1 resection (defined as microscopic involvement of the resection margins of the specimen) (51.9 months versus 22,01 months, $p = 0.039$) [46]. Although not statistical significant, extrahepatic tumor burden was associated with a poorer outcome in Niu's study (41.42 months for patients with liver confined disease versus 36.99 months for cases with both intra- and extrahepatic lesions ($p = 0.290$)).

Table 2. Studies regarding the role of hepatic resections as part of secondary cytoreduction in relapsed ovarian cancer

Author, year	Period of the study	No. of cases	Median DFI from initial diagnosis to liver metastases (months)	Extent of liver resection	Type of resection(definition of optimal cytoreduction)	Residual disease	Associated visceral resections
Bosquet et al., 2006 [42]	1976-2003	35	NR	NR	Residual disease < 1cm	< 1cm: 29pts > 1cm: 6 pts	Bowel resection: 34.3% Other associated resections: 80%

Merideth et al., 2003 [32]	1976-1999	26	29.4	Right hepatectomy: 15.4% Left hepatectomy: 3.8% Segmentectomy: 69.2% Trisegmentectomy: 11.5%	Intra- and extrahepatic residual disease < 1cm	R0: 21 pts R1: 5 pts	Bowel resection: 42.3% Diaphragmatic resection: 50% Splenectomy: 7.7% Lung resection: 7.7% Lymph node dissection: 15.4% Cholecystectomy: 9.2%

DFI: disease free interval; RFA: radiofrequency ablation.

Table 3. Early postoperative outcomes and long term results after liver resection for ovarian cancer liver metastases as part of secondary cytoreduction

Author, year	Period of the study	No. of cases	Postoperative complications	Hepatic surgery related complications	30 days postop. mortality rate	Median overall survival (months)
Bosquet et al. 2006 [42]	1976-2003	35	2.9% of patients required reoperation (small bowel fistula)	0	0	27.4
Niu et al. 2012 [46]	2000-2011	60	10% (pulmonary complications, wound infections)	0	0	39
Abood et al. 2008 [48]	1998-2006	10	10% (anemia requiring transfusion occurred in one case)	10%	0	33
Kolev et al. 2014 [49]	1988-2012	27	11% (two anastomotic leaks requiring reoperation and one postoperative sepsis)	NR	0	56 months – from the time of the diagnosis
Yoon et al. 2003 [30]	1988-2001	24	21% (two bilomas, one case of ileus, one case of urinary tract infection, one case of pneumonia)	8.3%	0	62
Roh et al. 2011 [47]	1991-2008	18	The rate of major complication was 5.6% (one case of transverse colon perforation). Five other patients experienced minor complications (ileus, wound infection, bile leakage, transient abnormality liver function or pleural effusion)	NR	0	38
Pekmezci et al. 2010 [50]	2003-2008	8	0	0	0	NR, disease free survival after liver resection=39 months
Merideth et al., 2003 [32]	1976-1999	26	7.6% (wound infection in one case and small bowel perforation requiring reoperation in the second case)	0	0	26.3

In the study conducted by Roh et al. including 18 patients resection margins of the hepatectomy specimen and residual disease were both associated with an improved survival.

Patients presenting negative resection margins experienced a significantly improved survival when compared to those with positive resection margins (40 months versus 9 months, $p = 0.0196$) while patients submitted to an optimal cytoreduction (defined as residual disease $< 1\text{cm}$) reported a median overall survival of 40 months, significantly higher when compared to those with suboptimal cytoreduction (median overall survival of 9 months, $p = 0.0004$) [47]. Optimal cytoreduction (defined as extrahepatic and intrahepatic residual disease $< 1\text{ cm}$) was also associated with an improved survival (27.3 months versus 8.6 months, $p = 0.031$) in Melissa Meredith's study conducted at Mayo Clinic, Rochester between 1976 and 1999 [32].

Based on these findings, the authors concluded that hepatic resection should only be considered if optimal cytoreduction is feasible [32, 47]. Similar results were also obtained by other studies, demonstrating that the tumoral burden as well as the diameter of the metastatic tumor are important prognostic factors and patients submitted to cytoreduction in the presence of extrahepatic disease should be carefully selected [47, 48].

Disease Free Survival

It has been advocated that patients with an increased disease specific survival from the primary surgery for ovarian cancer to the moment of liver resection have an improved outcome. In Bosquet's study patients with disease specific survival longer than one year also experienced an improved survival after liver resection (31.7 months versus 15.1 months, $p = 0.01$) [42]. Similar results were also reported by Niu's study, with a significantly improved median overall survival for patients with disease free survival of more than 12 months between ovarian cancer surgery and diagnosis of liver metastases (50.96 months versus 30.94 months, $p = 0.018$). The same authors stated that the improved results obtained after liver resections in patients with an initial longer disease free survival might be a reflection of a biologically indolent tumor [46]. In Kolev's study involving 27 patients a disease free survival after the initial treatment of 24 months was found to be statistically significant ($p = 0.044$) [49]. One of the most suggestive studies which demonstrates that the patient selection is crucial comes from S.S. Yoon et al. and was conducted at Memorial Sloan Kettering Cancer Center between June 1988 and December 2001. All patients included in this study had a relatively slow tumor progression and initially chemosensitive disease; this fact is demonstrated by the long disease free survival between the diagnosis of ovarian cancer and the apparition of liver metastases (with a median reported disease free interval of 68.5 months). In the meantime, the reported median overall survival was 62 months, although 75% of patients had extrahepatic tumoral burden [30]. Pekmezci et al. also considered that a longer disease free survival after the initial surgery for ovarian cancer is the mark of a good biological tumor behavior and considered these cases as the ideal candidates for secondary cytoreduction; the authors included in their study eight patients who developed liver metastases after a median disease free survival of 5.38 years; in the meantime the authors reported a secondary disease free survival after liver resection of 39 months which also favors the hypothesis of a less aggressive biology of the tumor [50]. Mayo Clinic reported similar results with a median overall survival of 27.3 months for patients with initial disease free

survival longer than 12 months versus 5.7 months for patients with a shorter initial disease free survival ($p = 0.004$) [32]. Oppositely to these results, in Hyun Jin Roh's study conducted on 18 patients, time from initial diagnosis to liver resection did not significantly impact on survival [47].

Number and Distribution of the Hepatic Lesions

The benefits of liver resection in patients presenting multiple lesions have been widely studied in colon cancer. In a study conducted by Bolton et al. patients submitted to liver resection for colorectal hepatic metastases were divided in to subgroups: cases with fewer than three liver metastases and cases with more lesions. The authors demonstrated that if all the lesions were resected, there was no difference in terms of survival between the two groups [54]. More recently, in order to find out if there is any limit regarding the maximum number of metastases which could be resected in liver metastases from colorectal cancer, an international panel of multidisciplinary experts decided that there is no limitation in regard to the number of excised lesions [55].

When it comes to ovarian cancer, although a higher number of hepatic lesions and a bilobar distribution might be considered as a poor prognosis factor, the reported results are inconstant. In Bosquet's study neither the number nor the distribution of the hepatic metastases presented statistical significance in terms of survival [42]; similar results were also reported by Kolev et al., and Merideth et al. respectively, no significant difference being revealed between cases with solitary liver masses and multiple lesions [32, 49]. Oppositely to these studies, Niu et al. reported an improved survival for patients diagnosed with a single metastases versus those with multiple lesions (55.4 months versus 26.06 months, $p = 0.018$). However, this fact did not reach statistical significance in multivariate analysis ($p = 0.085$) [46]. The diameter of the largest liver metastasis was proven to have a significant importance in Gerard Abood's study, conducted at Loloya University Medical Center, in which 10 patients were included. According to this study, tumor size larger than 5 cm was associated with a significantly increased survival (with a reported median survival of 17.2 months versus 11.2 months in patients with smaller tumors, $p = 0.046$); the authors explained this surprising aspect by the fact that cases with larger tumors have in fact less hepatic tumor burden due to the smaller number of lesions [48].

Other Prognostic Factors

When it comes to other possible prognostic factors such as the tumor histology and degree of differentiation, no significant influence in terms of survival has been demonstrated [32, 42, 46]. In the study conducted by Yoon et al. a favorable tumor biology (reflected in a slow growing pattern, limited to liver disease and long disease free interval) associated with a good biological status of the patient represents the ideal scenario for performing liver resection for ovarian cancer metachronous hepatic metastases [30]. An interesting aspect was revealed by Roh's study which demonstrated that a higher upper abdominal burden is significantly associated with a decreased survival (patients with a higher pelvic tumor burden

reported a median overall survival of 38 months while with those with a higher upper abdominal burden reported a median overall survival of 11 months, $p = 0.032$) [47].

The Significance of Hematogenous Hepatic Metastases in the Setting of Relapsed Stage Ovarian Cancer

In order to determine if a difference in terms of survival is maintained at the moment of secondary cytoreduction for peritoneal versus hematogenous lesions, a study involving 15 patients was conducted in Fundeni Clinical Institute, Bucharest. Disease free interval between surgery for ovarian cancer and diagnosis of liver metastases was 30 months. An R0 resection (defined as no residual tumor) was achieved in 12 patients. The histopathological findings revealed the presence of peritoneal lesions in six patients while in the other nine patients entirely parenchymatous lesions have been found. When it came to the type of liver resection, minor hepatectomies (defined as liver resection of less than two segments) were performed in 14 cases while in the fifteenth case a major hepatectomy was performed. In order to maximize the cytoreductive effort, associated visceral resections were performed: splenectomy (in four cases), bowel resection (in four cases), diaphragmatic resections (in three cases) and subtotal gastrectomy (in a single case).

The postoperative morbidity rate was 27% while the liver surgery related complication rate was 13% and consisted of biliary leak and a hepatic abscess respectively. Although it did not present statistical significance, patients with liver metastases with peritoneal origin had a better outcome when compared to those with hematogenous lesions (14.51 months versus 6.16 months, $p = 0.197$). However, liver resection proved to be a safe and effective method as part of secondary cytoreduction [41].

In conclusion, hepatic resection for metachronous liver metastases from ovarian cancer can be safely performed at the time of secondary cytoreduction with acceptable rates of postoperative liver related complications and almost zero mortality. However, mixed surgical teams including hepato-bilio-pancreatic surgeons, visceral surgeons and gynecologic oncologist should be created in order to maximize the effects of this aggressive surgical approach and to minimize the postoperative complication rates [42-45].

LIVER RESECTION BEYOND SECONDARY CYTOREDUCTION FOR RELAPSED OVARIAN CARCINOMA

Data regarding the place of liver resection beyond tertiary cytoreduction are even scarcer, limited number of cases being reported. In the same study conducted in Fundeni Clinical Hospital, liver resection was performed in three cases as part of tertiary cytoreduction and in two patients submitted to quaternary cytoreduction. Liver resection at the moment of tertiary cytoreduction was performed after a mean interval of 54 months after the initial diagnosis. In two cases minor hepatectomies (defined as resection of less than 2 segments) was performed while in the third cases a major hepatectomy was performed. Postoperatively death occurred in a single case due to the development of a urinary fistula after synchronous resection of a pelvic recurrence. The postoperative course uneventful in the other two cases; the long term

outcomes revealed a survival of 63 months for one case and 70 months for the second patient, the latter being alive at the moment of ending the study. As for the patients submitted to liver resection as part of quaternary cytoreduction,, the interval between the primary and quaternary cytoreduction was 40 and 33 months respectively. None of the patients experienced postoperative complications while the reported survival after quaternary cytoreduction was 16 and 20 months, both patients being dead of disease by the end of the study [41].

In another similar study conducted by Mario Leitaó in which 26 patients submitted to tertiary cytoreduction liver resection was necessary in three cases: in two cases wedge resections were performed while in the third case a segmentectomy was necessary to resect the hepatic lesions with negative margins. The postoperative morbidity rate was 27% while the overall mortality rate was zero. However liver surgery related complications were not reported [56].

In the study conducted by K.K. Shih et al. regarding the role of cytoreductive surgery beyond tertiary cytoreduction, a single patient submitted to quaternary cytoreduction had recurrent disease in the liver at the preoperative imagistic studies [57].

LAPAROSCOPIC AND ROBOTIC APPROACH FOR OVARIAN CANCER LIVER METASTASES

Once the safety and effectiveness of laparoscopic and robotic techniques have been widely demonstrated, these minimally invasive techniques became more frequently used in liver surgery too. The main advantages consist of implementing a minimally invasive procedure which assures a rapid postoperative rehabilitation without compromising the oncologic outcomes. The first robotic procedure performed in a patient with liver recurrence after ovarian cancer came from Robert Holloway and was performed in Florida in 2010. It was the case of a 60-year-old patient diagnosed with a 3.4 cm liver metastasis developed on the dome of the right liver, invading the diaphragm which was successfully resected robotically, after a console time of 82 minutes; the estimated blood loss was 100 ml. Postoperatively she developed a pleural effusion which was punctured, the patient being discharged on the fifth postoperative day. She was submitted to adjuvant chemotherapy 4 weeks postoperatively [58].

Utility of Radiofrequency Ablation in Association with Liver Resection for Ovarian Cancer Hepatic Metastases

In an attempt to increase the rate of complete cytoreduction and in the meantime to decrease even more the rate of postoperative liver surgery related complications some studies focused on the possibility of association of radiofrequency ablation in the setting of advanced stage and relapsed ovarian cancer with liver involvement [59-61]. However, the utility of radiofrequency ablation was initially proved in patients with liver metastases from colorectal cancer, data regarding the utility of the method in ovarian cancer liver metastases still being scarce [60-64]. Although in cases with liver metastases from colorectal cancer radiofrequency

ablation seems to be unjustified in the presence of extrahepatic disease, when it comes to ovarian cancer, it is perfectly justified in order to maximize the cytoreductive effort [59-61].

The main benefit in radiofrequency ablation is the fact that it provides a rapid, bloodless destruction of the hepatic lesion; in the meantime this method creates a circumferential coagulative necrosis of the surrounding liver parenchyma decreasing in this way the blood loss in cases in which hepatectomy is intentioned as the second step procedure. However, the method is still limited in cases presenting centro-hilar lesions: in these cases the close proximity of the large blood vessels will induce a “heat sink” effect, decreasing in this way the likelihood of complete ablation and secondarily increasing the risk of recurrence. In the meantime it can increase the risk of biliary fistula [28,65]. Another limitative factor remains the dimension of the lesions, lesions larger than 5 cm being associated with a higher risk of recurrence; however this risk can be decreased if radiofrequency ablation is followed by liver resection [28]. The method of radiofrequency ablation of liver metastases seems to be especially effective in patients with disseminated, bilobar parenchymatous lesions, in an attempt to spare as much as possible the healthy parenchyma without compromising the oncological outcomes. In the meantime peritoneal lesions seem to be best treated by classic surgical approach. In this way combining the two methods might maximize the cytoreductive effort [60].

In one of the most recent published series, Petrou et al. included 145 consecutive patients diagnosed with liver metastases from various primaries submitted to radiofrequency ablation assite liver resection in order to decrease the blood lost during surgery. The standard technique in these cases consists of applying the radiofrequency ablation needle along the line of parenchymal transection in order to create at this level an area of bloodless coagulative necrosis. By applying this principle, it is estimated that liver ischemia-reperfusion injury which usually develop after partial or total vascular occlusion could be safely minimized. Among the 145 patients submitted to radiofrequency ablation followed by liver resection, ovarian primaries were reported in two cases; in one case radiofrequency ablation was followed by a minor hepatic resection while in the latter case a major hepatectomy was associated. After performing these maneuvers, liver tests were slightly elevate during the early postoperative period and were normalized within seven days after surgery. When it comes to the completeness of resection, an R0 resection was achieved in 114 patients while in the other 13 cases an R1 resection was performed, the remnant 18 patients being submitted to liver resection for benign conditions. Regarding the postoperative outcomes, morbidity developed in 47 cases, no-one requiring re-operation. The most common complication remained transient liver insufficiency, which was completely recovered in all cases. Postoperative bile-leaks developed in ten patients, the mean duration of the leak being 17 days (range 5-32 days). However the postoperative complication rates were similar between cases submitted to major versus minor resections, demonstrating the safety and efficacy of the method [66].

In the case series reported by Mateo et al. three patients submitted to liver resection and radiofrequency ablation were included. The first reported case was a 59-year-old woman initially diagnosed with a stage IV ovarian cancer for which she was submitted to neoadjuvant chemotherapy followed by optimal debulking surgery. Five years later the patient was diagnosed with isolated hepatic recurrence (located in segment VI according to Couinaud’s classification). Intraoperatively the lesions were successfully resected; however the intraoperative ultrasound revealed the presence of other two lesions located in the caudate

lobe, each one measuring less than 2 cm which were successfully ablated. Several peritoneal nodules were also found and resected, achieving a complete resection. At 13 months follow up the patient had no recurrent disease. The second reported case was the one of a 51-year-old patient initially diagnosed with stage III ovarian cancer for which she was submitted to debulking surgery followed by other two cytoreductive procedures for relapsed disease. Seven years after the initial diagnosis the patient was diagnosed with two liver metastases: the first one was developed on the right hepatic dome invading the diaphragm which was successfully resected while the second one measuring 2.8 cm was located in the proximity of the right hepatic vein and of the anterior branch of the right portal vein and was treated by radiofrequency ablation. At nine months follow up there was no sign of recurrent disease. In the third case radiofrequency ablation was the treatment of choice for a late recurrence after a stage III ovarian granulosa cell tumor. The patient had been previously submitted to surgery 19 years before, followed by adjuvant chemotherapy. At the time of recurrence she was diagnosed with an 18 cm tumor developed in the right hemiliver associated with a 2.5 cm lesion located in segment IV. The largest lesion was resected by an extended hepatectomy was the segment IV lesion, which was ablated by radiofrequency. Although the patient refused any adjuvant chemotherapy, she was free of any recurrent disease at 39 months follow up [60].

All of these encouraging results come to underline the benefits of association between radiofrequency ablation and liver resection for advanced stage or relapsed ovarian cancer with liver involvement.

ABSTRACT

Introduction and aim: The aim of the informed consent cannot only be to comply with what is established by the law. It must be a process of communication between the doctor and the patient which is the basis of a relationship based on trust. This will improve the quality of the assistance that the patient receives by diminishing his anxiety through the information provided. The aim of the research described in this chapter is to evaluate the effect of informed consent format on preoperative anxiety of patients. Besides, we are attempt to analyze the influence of anxiety (both state and trait) in postoperative recovery of the patient submitted to the extraction of mandibular third molar, and also to establish the role of each types of anxiety in the results obtained in an independent and complementary way.

Material and methods: We carried out two prospective studies. The first one was performed in 91 patients undergoing lower third molar extraction. Patients were distributed in three groups and informed consent was provided through a written document, a verbal interview and a video recording. Then, patients were asked about their anxiety level and the effect that the informed consent have had on it. The second study included 88 patients, the intervention performed was the extraction of the third molars and subjects were asked to complete the Spielberger State-Trait Anxiety Inventory - Trait and State before receiving any information about the surgical procedure. The study evaluated postoperative swelling and pain.

Then patients were asked to fill out a 10-point visual analog scale (VAS) at home every day, 8 days after the surgery, until sutures were removed.

* Corresponding Author's Email: jlgp@us.es; Fax: 95.448.11.11.

Results and discussion: While the results showed that the information provided to patients in oral and written formats were useful to relieve their anxiety (in a scale of -3 to +3) 0.97 ± 1.21 and 0.29 ± 0.97 , respectively), the video recording increased patient's anxiety in a statistically significant way (in a scale of -3 to +3, -0.57 ± 1.43). The difference obtained between the values obtained in oral and written information was not statistically significant. Regarding postoperative outcomes between positive and negative trait anxiety groups, results showed that the consumption of analgesics was higher in positive trait anxiety group, while differences between both groups regarding pain and swelling were detected only on specific moments. The relation between the informed consent format, the level of anxiety, and the postoperative outcomes, can provide new lines for future research to improve the clinical assistance and the best use of informed consent.

1. INFORMED CONSENT

One of the most important responsibilities of a healthcare provider is to ensure that before any clinical procedure is undertaken the patient has been provided with all the information concerning the surgery. Mainly, this implies explaining to the patient the reason why it is necessary to undergo this procedure, also giving him relative information such as associated complications, risks and benefits, without forgetting any possible alternative treatment. Normally, the consent of a patient undergoing a surgical procedure must be obtained. Because, even though the goal of the procedure is to improve their health, a risk of an injury or any other negative outcome or complications could also be encountered.

This process, based on patient-doctor communication, is known as 'informed consent' whose main purpose is providing enough information to allowing the patients to understand their treatment and to be voluntarily submitted to the intervention. Nevertheless, although the doctor tries his best, sometimes patients are not able to retain all the information received or to express their questions for a better understanding. That is the reason why nowadays, there is a growing interest in improving the quality of informed consent given to the patients, including not only oral or written communication, but also the availability of videos and websites. To protect human rights, some organizations such as General Medical Council or American Medical Association, among others, have reached consensus concerning the information that healthcare community should give to patients during the informed consent. For that, scientific community has created international guidelines such as Declaration of Helsinki (DoH 2001, 2009) of the World Medical Association. Referring to informed consent, the requirements to be considered it valid are the following [1, 2]:

- The patient has to understand the information provided by the healthcare professional.
- The individual must be able to retain the information long enough to make a decision.
- The patient must be capable to ponder the information as part of the decision-making process.
- The individual can communicate openly his decision.

In some cases, problems with informed consent can appear when doctors underestimate or undervalue the information that patients need [4]. It could be due to that the clinicians may overestimate the amount of information they explain [5], they could have a lack of skills in passing this information [6] or use specific technical language. The UK Department of Health emphasizes that when all the relevant information has not been given adequately to patients, when individuals are not capable to understand correctly or they have had not the chance to ask doubts, the consent may not be valid although the patient has signed it. Furthermore, with a proper verbal informed consent, even if the consent form is not signed, is not considered a barrier to proceed the treatment. Moreover, some doctors usually focus on communicating technical risks or negative outcomes relative to surgical procedure, for example, a wound infection, nerve injury or other specific complications [7].

These possible risks could be of concern to patients, but this approach overrides the awareness about other problems of greater importance. These complications can include pain or more days of inability at work [8]. Ideal circumstances would be that doctors could talk to patients at least two or three times before the surgical procedure. This gives the patient the time to think about the given information and to make the right decision about undergoing an operation. Nevertheless, when the consent form has been signed and thus, the formal consent discussion is considered understood, the patient usually has no more interviews until the intervention. That is the reason why informed consent procedure has become a routine process that does not allow enough time to the patients for considering their decision [9]. One of the reasons for this problem regarding the informed consent routine, can be due to a standardized consent form which makes the process seems repetitive to doctors. This can also affect the clinician making him more desensitized to patient's fears and concerns, because doctor can view the surgical procedure commonplace and routine [10]. However, any standardization of this procedure could have the problem of not promoting patient autonomy [11]. Particularly, only a percentage of 41% of patients believe that informed consent is useful to clear their doubts and the 46% believe that the main purpose of the consent form is to protect the hospital [12]. Ensuring a quality consent form presents challenges for both doctors and healthcare organizations. It has been reported that patients who received enough information were more likely to undergo conservative treatment with the consequence of declining surgical procedures, thus reducing overall health costs [13]. On the one hand, one of the main causes of formal complaints and costly litigation is due to a failure regarding the informed consent. On the other hand, satisfactory information provides extra benefits for patients, such as greater satisfaction, more rapid recovery, reduction of anxiety, and thus, a decrease in the use of analgesics and other drugs [14, 15].

2. INFORMED CONSENT IN ORAL SURGERY

Informed consent is one of the basic principles of the current surgery. It is considered a result of a satisfactory communication between doctor and patient, and the basis on which the clinical setting is established. It's not only a fundamental right of patients, but also an ethical and legal requirement for clinicians. As it was explained, this legal document must be submitted and signed before surgery and allows that patient authorizes the intervention recognizing that he has been informed sufficiently about benefits, risks and possible treatment

options. In the consent form, the consequences of the intervention should be exposed as well as typical, atypical and exceptional risks which must be included due to its severity or its relationship with the personal circumstances of the patient. In short, informed consent must cover four key areas: need of treatment, its risks, benefits and alternatives [16].

- ❖ Informed consent must include the following information:
 - Patient's name and name and number of clinician.
 - Treatment that will be carried out detailing the procedure and the purpose that is expected.
 - Information relative to consequences, possible discomfort, typical and atypical risks to which the patient is exposed.
 - Alternative treatments.
 - Declaration that patient has understood the information provided.
 - Expression of consent.
 - Date and signature of patient and doctor.
 - Section for withdrawal of consent.

Informing the patient can not only be a legal requirement, it is also one of the techniques used to reduce preoperative anxiety of patients. Many studies have reached consensus that providing quality information about intervention is beneficial because patients feel they have more control over the situation so his psychological stress is reduced and his preoperative anxiety decreases [17, 18]. Besides, this offers benefits in both objective and subjective improvement of patient recovery process [19]. In other words, not receiving information increases the feeling of anxiety [20] but also the level of satisfaction [21].

Unlike other interventions of general surgery, dental surgery, in most cases, are performed with the patient awake and under local anesthesia, hence, informing the patient previously before the intervention helps to decrease his fears and anxiety which also positively influences in the postoperative outcomes [22].

It has been proposed that patients who did not receive adequate medical information showed high levels of state anxiety in STAI test [23] and patients with high levels of anxiety-state usually demand more information [24, 25]. From this topic, health community is shrouded in controversy. While some authors ensure that medical information can increase levels of anxiety and also influence in the number of postoperative complications [26], from another point of view, several publications reported that providing detailed information can increase levels of anxiety and stress [27].

There is an interesting study with objective results about how information can influence in physiological changes of patients submitted to third molar extraction surgery. To measure the increase of anxiety, they analyzed the pulse of the patient [28].

❖ Informed consent formats

Unfortunately, the best methodology of informed consent is not legally defined, neither the quality nor the quantity of the information that must be given to the patient [29]. What we must be sure of is that the patient has understood the information provided using a simple language, avoiding jargon and adapting it to their individual and personal characteristics [30]. The informed consent information can be offered in different formats [16].

➤ Detailed / Brief format:

Regarding to the amount of information, there is no consensus about the maximum or the minimum information that must be given to the patient. In general, protocols must be generic and, for each patient the doctor may complete it by adding specific risks and complications of the procedure. Studies show that patients suffer less preoperative anxiety if the information provided is extensive and detailed than if it is too brief [31].

However, giving too much information can produce an increment of anxiety and restlessness. According to wisdom teeth removal, it is essential to highlight in the preoperative information two possible complications that may have relevant consequences for the patient and therefore, important legal implications: damage to the inferior alveolar nerve or to the lingual nerve with loss of sensitivity or paresthesia [29].
